

INFORMATION TO USERS

This dissertation was produced from a microfilm copy of the original document. While the most advanced technological means to photograph and reproduce this document have been used, the quality is heavily dependent upon the quality of the original submitted.

The following explanation of techniques is provided to help you understand markings or patterns which may appear on this reproduction.

1. The sign or "target" for pages apparently lacking from the document photographed is "Missing Page(s)". If it was possible to obtain the missing page(s) or section, they are spliced into the film along with adjacent pages. This may have necessitated cutting thru an image and duplicating adjacent pages to insure you complete continuity.
2. When an image on the film is obliterated with a large round black mark, it is an indication that the photographer suspected that the copy may have moved during exposure and thus cause a blurred image. You will find a good image of the page in the adjacent frame.
3. When a map, drawing or chart, etc., was part of the material being photographed the photographer followed a definite method in "sectioning" the material. It is customary to begin photoing at the upper left hand corner of a large sheet and to continue photoing from left to right in equal sections with a small overlap. If necessary, sectioning is continued again — beginning below the first row and continuing on until complete.
4. The majority of users indicate that the textual content is of greatest value, however, a somewhat higher quality reproduction could be made from "photographs" if essential to the understanding of the dissertation. Silver prints of "photographs" may be ordered at additional charge by writing the Order Department, giving the catalog number, title, author and specific pages you wish reproduced.

The Reactions of Methylene with
Isobutane and Cyclopropane

SUMMARY

Research Director:
George B. Kistiakowsky

Barbara Breidenbach Saunders
February 1972

Ketene was photolyzed at several wavelengths in the presence of large amounts of either isobutane or cyclopropane.

The ketene-isobutane mixture was photolyzed at 214 nm, 277 nm, 313 nm, 322 nm, and 330 nm and the variations in the percentages of methylene in the triplet and singlet states, as reflected in the distribution of products, were studied. Additional photolyses in the presence of varying amounts of CO or O₂ were able to clarify the mechanism of CH₂(³B₁) production. The absorption of light at the longest wavelengths (330nm and beyond) is primarily the result of the ³A₂ ← ¹A₁ transition in ketene. At 330nm, 75% of the CH₂ resulting from the photodecomposition of ketene (³A₂) was in the ³B₁ state. At 277 nm, all of the absorption is attributed to the ¹A₂ ← ¹A₁ transition and, hence, all of the CH₂ produced from the ketene decomposition is in the ¹A₁ state. At all wavelengths, the bimolecular crossing from CH₂(¹A₁) to CH₂(³B₁) competes with the reaction of CH₂(¹A₁) with isobutane and almost 50% of the CH₂(¹A₁) is converted by the isobutane to CH₂(³B₁). The photolysis of ketene at the intermediate wavelengths is characterized by a mixture of the three processes. Absorption of radiation at 214 nm excites ketene to its second excited singlet state, ¹A₁, and there is some evidence that the CH₂ produced from the decomposition of this state is CH₂(¹B₁).

The ketene-cyclopropane mixture was photolyzed in the presence of 5% O₂ at 214 nm, 277nm, 313 nm, and 330 nm in order to study the unimolecular decomposition of methylcyclopropane (formed by the reaction of CH₂(¹A₁) and cyclopropane) containing different amounts of energy. The rate of decomposition was largest when 214 nm radiation was used and decreased as the photolyzing energy decreased. The RRKM theory was used to estimate the amount of energy in the excited methylcyclopropane molecule. The difference in decomposition rates was used to estimate the fraction of the photolysis energy that CH₂(¹A₁) carried to the cyclopropane.

To the men I love, especially my husband, Kim.

I would like to thank my research director, Prof. George B. Kistiakowsky, for the help and support he has given me. Dr. Jerry Bell kindly lent me a copy of C. J. Mitschele's Thesis, and his discussions with me were very helpful.

I would like to acknowledge the Woodrow Wilson Foundation and the National Air Pollution Control Administration for their financial support.

I am indebted to my colleagues at Harvard whose friendship and encouragement kept me working when the laboratory seemed against me; a very special thanks to Michael J. Berger, William P. Haugen, Thomas Izod, Lynn Melton, and John and Elizabeth Marlow.

I especially thank my husband, Kim, for his love, understanding, and patience, and, also, my dog, Schnapps, for her affection.

1 Introduction

The Structure of Methylene

The biradical methylene, CH_2 , is easily produced by the pyrolysis¹ or photolysis of diazomethane,³ the photolysis of ketene,³ the photolysis of diazirine,⁴ and by the vacuum ultraviolet photolysis of propane.⁵ Although its existence had been suspected since 1933, methylene eluded spectroscopic observation until 1959 when the careful and patient work of Herzberg and Shoosmith identified methylene in the ultraviolet flash photolysis of diazomethane in the presence of a large amount of nitrogen.⁶

Herzberg identified several different electronic states of methylene. The lowest energy or ground state is a triplet electronic state and appeared to be linear, a ${}^3\Sigma_g$ state. In 1970, the electron spin resonance spectrum of the triplet state of methylene⁷ as well as the latest theoretical calculations⁸ indicated that it was actually bent. This 3B_1 ground state was confirmed by Herzberg and Johns.⁹ The second electronic state is a bent singlet state, 1A_1 , and the third electronic state is another singlet state which lies about 30 kcal/mole above the 1A_1 state, the 1B_1 state. The geometries of all three states are very similar and except for the spin, the 1B_1 and 3B_1 states are described by the same configuration. In most chemical systems, there is not enough energy available to form the 1B_1 state and usually only two states are present, the 1A_1 and the 3B_1 states which are referred to as 1CH_2 and 3CH_2 . Table 1-1 summarizes the properties of the three states of methylene.

The Reactions of Methylene

Several excellent reviews¹⁰ have appeared which summarize and describe the reaction of methylene and the reader is referred to these for a more complete discussion of the reactions. Only those reactions pertinent to the studies in this thesis will be mentioned here.

Since at least two different electronic states of methylene exist, there is the possibility of at least two types of reactions everytime methylene reacts with a molecule. Both methylenes, $^1\text{CH}_2$ and $^3\text{CH}_2$, react with the C-C double bond in ketene and diazomethane, the C-H bonds in hydrocarbons,¹⁰ oxygen to form CO, CO₂, H₂; H₂O and other oxidation products,¹¹ and CO to form ketene.¹²

The $^3\text{B}_1$ state of methylene, $^3\text{CH}_2$, reacts more slowly with C-H

bonds than does the 1A_1 state of methylene, 1CH_2 .^{13,14} 3CH_2 effectively inserts into the C-H bonds of hydrocarbons in two steps, by abstracting an H atom from the hydrocarbon, RH, to form the methyl radical and an alkyl radical, R, which then recombine to finally form R-CH₂-H.¹⁰ Because of the recombination reactions, the reactions of 3CH_2 with a hydrocarbon also result in the formation of recombination products other than just those of the methyl radical recombining with the alkyl radical, e.g., R-R, CH₄, and olefins corresponding to RH-H₂ and C₂H₆. The reaction of 1CH_2 with C-H bonds involves a concerted insertion of the 1CH_2 between the C and H atoms. This reaction results in no products other than R-CH₂-H.¹⁰

The reaction of 3CH_2 with O₂ occurs faster than does the reaction of 1CH_2 with O₂.^{11,15} Since the addition of only a few percent of O₂ eliminates 3CH_2 as a reactant, the reactions of 1CH_2 can be studied. However, there is another method of determining the 1CH_2 reaction channels which makes use of more discriminating reactants than O₂. In methylene-hydrocarbon reaction systems,

14. Frey, H. M. and Walsh, R., J. Chem. Soc. (A) 1970, 2115

15. In a methylene-hydrocarbon system, the presence of O₂ can also eliminate the products of 3CH_2 reactions by reacting with the radicals formed after the abstraction reaction. There is an additional complication when ketene is photolyzed by wavelengths longer than about 320 nm. The photolysis of ketene in this region involves an excited triplet state of ketene which may react with O₂.

since the reaction of $^3\text{CH}_2$ with a C-H bond is slow, the presence of gases which are more reactive towards $^3\text{CH}_2$ than a hydrocarbon will prevent the reaction of $^3\text{CH}_2$ and the hydrocarbon. This technique has been used by DeGraff and Kistiakowsky^{12b} and Cox and Cventanovic¹⁶ to isolate $^1\text{CH}_2$ reactions by including relatively large amounts of CO in their ketene and ketene-hydrocarbon systems. Unlike O_2 , CO will not react with alkyl radicals and so some of the potential complications are absent.

Bell¹⁷ has shown that the reaction of $^3\text{CH}_2$ with diazomethane is so much faster than its reaction with the C-H bonds in propane, that the presence of even relatively small amounts of diazomethane prevent the reaction of $^3\text{CH}_2$ and propane. However, there are so many secondary reactions resulting from the reaction of $^3\text{CH}_2$ and diazomethane that this relatively fast reaction often makes the methylene-hydrocarbon system more complicated than when the diazomethane reaction is unimportant. The reaction of ketene with $^3\text{CH}_2$ is also faster than the reaction of $^3\text{CH}_2$ with C-H bonds; however, this reaction is not nearly as fast as that with diazomethane.

17. Bell, J. A., *J. Phys. Chem.* 75, 1537 (1971)

No previous work has been done which describes the reactions of the 1B_1 state of methylene, but on the basis of similar electron configurations, the 1B_1 state may react in the same way the 3B_1 state does.¹⁸ This is expected when the electronic orbital configuration of methylene is the most important factor in deciding the reaction pathway, such as in the reaction of CH_2 with O_2 and C-H bonds. In cases where the energy of the methylene is more important, the 1B_1 state should react more as the 1A_1 does. This is expected for the reaction of CH_2 and CO where the 3B_1 reacts to a greater extent than the 1A_1 or 1B_1 because of the formation of the metastable 3A_2 state of ketene. Upon reaction with CO, both the 1A_1 and 1B_1 states form excited singlet states of ketene which decompose very quickly. When ketene is photolyzed at 214 nm, enough energy is available to form methylene in the 1B_1 state. The results of our experiments with the ketene-isobutane system photolyzed at 214 nm indicate that methylene is present in the 1B_1 state and that the 1B_1 state reacts as the 3B_1 state does with the C-H bonds and O_2 .

Intersystem Crossing in Methylene

The photolysis of ketene, diazomethane, diazirine, or propane always produces both forms of methylene, $^1\text{CH}_2$ and $^3\text{CH}_2$. This has been verified spectroscopically^{6,13} and by the decrease in quantum yields of products upon the addition of oxygen or large amounts of carbon monoxide.^{12,17,19} Studies of the ketene photolysis system have shown that the relative amounts of $^1\text{CH}_2$ and $^3\text{CH}_2$ vary with photolyzing wavelength^{12b, 19, 20,22,10} and the concentration of non-reactive gases.^{22,24} Studies of the diazomethane photolysis system have shown that only the concentration of the non-reactive gases affects the relative amounts of $^1\text{CH}_2$ and $^3\text{CH}_2$; the concentration of the reactive gases does not affect the relative amounts.^{21,6,23} In both the ketene and diazomethane systems, direct spectroscopic observations of $^3\text{CH}_2$ have shown that the amount of $^3\text{CH}_2$ increases as the concentration of a non-reactive gas, e.g., He, increases. This was a very important discovery, for it meant that somehow a small, triatomic species

was able to cross-over from a singlet to a triplet electronic state, a process which is forbidden by quantum mechanics. Methylene is not the only small species in which this spin-forbidden process occurs,²⁵ but it is one of the lightest.

Such spin-forbidden processes are known among atoms, but only among the very heavy atoms, such as Hg, where the orbitals are considered to be so closely spaced that they interfere with the electron spin, or in other words, where the spin-orbit interactions are large, and thus the spin is not a good quantum number or a precise characteristic for the atom. In these cases, spin does not have to be conserved. A transition from a singlet electronic state to a triplet electronic state has long been known to occur in large polyatomic molecules, for example, in benzene, anthracene, and many organic dye molecules. Quantum theories explain such spin-forbidden transitions by assuming that very closely spaced vibronic levels within either the triplet or singlet manifold allow a matching of energy levels. The resultant transition moment can be calculated using Fermi's Golden Rule.^{25,26,27} However, such close spacing cannot occur in as small a triatomic species as CH₂.

Further experiments by Cox and Preston,²⁴ Eder and Carr,²² and Bell¹⁷ have established the importance of collisions in the intersystem crossing of CH_2 . The prevailing view of the intersystem crossing in the methylene system is that collisions are necessary to convert $\text{CH}_2(^1\text{A}_1)$ to $\text{CH}_2(^3\text{B}_1)$ and that the rate of this intersystem crossing can be related to the polarizability of the collision partner. Thus, if $\text{CH}_2(^1\text{A}_1)$ is present in any system which is free from oxygen or any other similar scavenger, $\text{CH}_2(^3\text{B}_1)$ is also present, and the amount of $^3\text{CH}_2$ will depend on the gases present in the reaction system.

Chemical Activation and Unimolecular Reactions

Methylene has often been used to study the unimolecular decomposition of energy rich hydrocarbons.²⁸ When methylene is used for this purpose, it is desirable to have only the $^1\text{A}_1$ state reacting with the hydrocarbon. There are four reasons for eliminating the reactions of the $^3\text{B}_1$ state: reactions of the $^3\text{B}_1$ state with the hydrocarbon (1) result in an assortment of closely related side products, (2) are slower than the reactions of the $^1\text{A}_1$ state and so the $^3\text{B}_1$ state will lose more energy

28. See, for example, the reviews by Bell and Frey, ref. 10 and Rabinovitch, B. S. and Flowers, M. C., *Quart. Rev.* 1964, 122.

through collisions and thus form a less energetic product, (3) proceed through a two step mechanism rather than a concerted insertion so that the separate radical intermediates may lose energy before recombining, and (4) will form a less energetic product than the 1A_1 state because at least some of the 3B_1 state is formed by the collisional conversion of the 1A_1 state. Thus, the reaction of 3B_1 methylene in a chemical activation system will result in an excited hydrocarbon which contains an ill-defined amount of energy.

Singlet methylene can be used to create a hydrocarbon which contains energy far in excess of that created by thermal collision (simple pyrolysis or thermal decomposition) and unlike thermal decompositions, this energy will be limited to a fairly narrow range. As the photolyzing energy used to decompose the ketene or diazomethane is increased, the average energy of the resulting hydrocarbon is also increased.^{29,30} The rate of decomposition is determined from the variation of the products' distribution with pressure. The theories which describe unimolecular decompositions can be used to analyze the experimental rate constant to obtain more detailed knowledge about the activated

complex, the configuration which the excited molecule must pass through just before decomposing, and the specific rate at which the excited molecule passes through this configuration.

There are many excellent discussions of the theories of unimolecular decomposition³¹ and only a brief summary of the pertinent points will be presented here for the purposes of definition. The following reaction scheme is consistent with the three major theories of unimolecular reactions. k_E is the specific frequency at which a molecule of energy E changes into the configuration of the activated complex, A^\ddagger . k_1 is the rate constant for thermal activation where the excited molecule, A^* , is produced by thermal collisions, and k_{bi} is the rate constant for chemical activation where the excited molecule is produced by chemical reaction.

In the theories of Kassel³² and Rice and Ramsperger³³, often known as the RRK theory, the excited molecule, A^* , is made up of a number of loosely coupled oscillators, s , (usually taken to be the molecule's normal modes of vibration or the individual

31. Laidler, K. J., Theories of Chemical Reaction Rates, 1969, McGraw-Hill, Inc. New York.

vibrating bonds) which are still separate enough to be described as normal modes and which, for convenience, are all assumed to be of the same frequency. Marcus³⁴ extended the RRK theory so that both the molecule and complex are made up of all the individual vibrations including each zero-point energy. The RRKM theory also includes the rotations of both the molecule and complex. In both theories, the available energy is statistically distributed among the vibrations, and reaction occurs when enough energy from all of the vibrations and participating rotations is concentrated in one vibration or rotation, the reaction coordinate, so that the bond breaks.

Slater³⁵ assumes that the molecular vibrations are not coupled and so no energy can be exchanged between them. He envisages the point of reaction to have occurred when the vibrations of the molecule cause the critical coordinate, for example, a bond length, to be extended to a specific length. A very detailed treatment of the individual vibrations is needed to apply Slater's theory if the decomposition is to be studied over a wide range of conditions.

Studies of several molecules have shown that Slater's treatment predicts rate constants far smaller than either were

34. Marcus, R. A., *J. Chem. Phys.* 20, 359 (1952).

35. Slater, N. B., *Proc. Camb. Phil. Soc.* 35, 56 (1939) and Theory of Unimolecular Reactions, Cornell University Press, Ithaca, New York, 1959.

observed or were predicted by the RRKM or RRK theories.³⁶ Thus, Slater's assumption that there is no energy flow between normal modes is incorrect. Further evidence was provided by Butler and Kistiakowsky³⁰ who used methylene to form methylcyclopropane by reactions with cyclopropane and propylene. No oxygen was used and so both the 1A_1 and 3B_1 states of methylene were reacting with the hydrocarbons. The methylcyclopropane formed from propylene will initially have the energy from the methylene concentrated in a different bond than when it is formed from cyclopropane. If there is no energy flow before decomposition, the distribution of butene isomers in the methylene-propylene system should be different from the distribution in the methylene-cyclopropane system. Butler and Kistiakowsky³⁰ found the same distribution of isomers in both systems which means that the energy was completely distributed before decomposition.

In the "classical limit", Slater's treatment is as good as the RRK treatment and both, although incorrect, can be useful approximations. When the average energy of the molecule, $\langle E \rangle$, is much larger than the critical energy necessary for decomposition, E_0 , the molecule and complex, to a good approximation, can be treated classically. In this classical limit, the expressions for

36. See for example ref. 31 and also Gill, E. K. and Laidler, K. J., Proc. Roy. Soc. A250, 121 (1959).

k_E in both the RRK theory and Slater's theory simplify to

$$k_E = k^\ddagger \left[\frac{\langle E \rangle - E_0}{\langle E \rangle} \right]^{s-1} \quad (1)$$

The high pressure limit of thermal decomposition, k_∞ , in both theories is

$$k_\infty = k^\ddagger \exp(-E_0/kT) \quad (2)$$

Thus, k^\ddagger corresponds to the frequency factor in the high pressure limit and can be determined from an Arrhenius plot of the high pressure limit of thermal decomposition at several temperatures.

RRKM Theory

A great deal of work has been done using the RRKM theory.^{28,31,37} The expression for k_E has the form

$$k_E = \frac{1}{h} \frac{Z_1^\ddagger}{Z_1^*} \frac{\sum P(E_{vr}^\ddagger)}{N^*(E_{vr})} \quad (3)$$

Z_1^\ddagger and Z_1^* are the products of the partition functions of the degrees of freedom which do not contribute to the energy available for decomposition (the adiabatic degrees of freedom) for the activated complex and molecule, respectively. h is Planck's constant and $E_{vr}^\ddagger = E - E_0$, where E is the energy of the molecule. $\sum P(E_{vr}^\ddagger)$ is

37. For reviews see Rabinovitch, B. S. and Flowers, M. C., *Quart. Rev.* 1964, 122 and Spicer, L. D. and Rabinovitch, B. S., *Ann. Rev. Phys. Chem.* 21, 349 (1970).

the sum of the degeneracies of all the eigenstates of the active degrees of freedom (vibrational and rotational) for the activated complex at energy E_{\ddagger} , and $N^*(E_{\text{vr}})$ is the energy density of the active degrees of freedom for the molecule at energy E . The expressions for $\sum P(E_{\text{vr}}^{\ddagger})$ and $N^*(E_{\text{vr}})$ are:

$$\sum P(E_{\text{vr}}^{\ddagger}) = \frac{Z_r^{\ddagger}}{(kT)^{r^{\ddagger}/2} \Gamma(1 + r^{\ddagger}/2)} \sum_{E_v^{\ddagger}=0}^{E^{\ddagger}} P(E_v^{\ddagger}) (E^{\ddagger} - E_v^{\ddagger})^{r^{\ddagger}/2};$$

$$r^{\ddagger} \neq 0.$$

$$P(E_{\text{vr}}^{\ddagger}) = \sum_{E_v^{\ddagger}=0}^{E^{\ddagger}} P(E_v^{\ddagger}); \quad r^{\ddagger} = 0$$

and

$$N^*(E_{\text{vr}}) = \frac{Z_r^*}{(kT)^{r^*/2} \Gamma(r^*/2)} \sum_{E_v=0}^E P^*(E_v) (E - E_v)^{r^*/2 - 1};$$

$$N^*(E_{\text{vr}}) = \left[\frac{\partial \sum_{E_v=0}^E P^*(E_v)}{\partial E} \right]_{E_v=E} \quad ; \quad r^* = 0.$$

Z_r is the partition function for r active internal rotations and overall rotational degrees of freedom. $P(E_v)$ is the degeneracy of the vibrational eigenstate E_v . The stars and daggers refer to properties of the molecule and activated complex, respectively.

Further details of the theory and methods of evaluating the eigenstates are given in the review article by Setser and Rabinovitch.³⁸ A computer program which evaluates the vibrational eigenstates as described by Whitten and Rabinovitch³⁹ and which calculates k_E at specified energy intervals when the other parameters are included is available from Professor B. S. Rabinovitch and is described in the review article by Setser and Rabinovitch.³⁸

The Present Work

The experiments described in this thesis are in two parts. The first part of the thesis describes the reaction of the 1A_1 , 3B_1 , and 1B_1 states of methylene with isobutane, the different absorption regions of ketene, and the rate of intersystem crossing in the methylene system. The second part is a study of the reaction of the 1A_1 state of methylene, 1CH_2 , with cyclopropane and the subsequent decomposition of methylcyclopropane into its four butene isomers. The source of methylene was ketene photolyzed at several wavelengths (214 nm, 277 nm, 313 nm, 322 nm, and 330 nm) chosen to represent each of the three absorption

38. Setser, D. W. and Rabinovitch, B. S., *Adv. Photochem.* 3, 1 (1964).

regions in the near ultraviolet absorption spectrum of ketene. Oxygen and carbon monoxide were used to distinguish between the reactions of the different states of methylene in the isobutane experiments. Oxygen was used to eliminate the reactions of the 3B_1 and 1B_1 states with cyclopropane. Professor B. S. Rabinovitch kindly supplied us with the computer program used in analyzing the decomposition of methylcyclopropane.

2 Apparatus and Techniques

Preparation of Ketene

Ketene was prepared by the pyrolysis of acetic anhydride at 520°C and was purified by subsequent trap to trap distillations.¹ After degassing, the acetic anhydride was slowly let into a warm flask (180°C) via a dropping funnel (see fig. 1-1). The liquid was vaporized in the flask and the gaseous acetic anhydride went into the quartz pyrolysis tube which was kept at 520°C. The pyrolyzed gas contained ketene, acetic acid, and unreacted acetic anhydride. The ketene passed through the dry ice-isopropanol trap and condensed in the liquid nitrogen trap; the acetic acid and acetic anhydride remained in the dry ice-isopropanol trap. Three trap to trap distillations using dry ice-isopropanol and liquid nitrogen further purified the ketene which was stored under liquid nitrogen to prevent decomposition and polymer formation. The ketene dimer forms fairly rapidly at vapor pressures of ketene above 100 Torr. Ketene prepared in this way contained less than 100 ppm of ethylene, ethane, and acetylene as determined by mass spectrometric analysis.² When analyzed on the gas chromatograph, ketene samples which were passed through the columns at temperatures up to 100°C showed no change in the size of the ethylene peak and no ketene. (Ethylene was the major impurity

in the ketene.) Presumably the ketene sticks to the column and does not decompose to ethylene and CO once it is in the column.

Spectral Regions and Lamps Used for Photolysis

Most of the photolyses were done with an Osram HBO-500 Watt mercury super pressure lamp used in conjunction with a Bausch and Lomb (#33-86-01) grating monochromator. The spectral distributions were determined for specific monochromator settings by use of a (Jarrel-Ash, model 82-000) Ebert spectrometer and RCA-1P28 photomultiplier. The spectral distributions are shown in figure 2-2 and for easy reference, the position of maximum intensity for each setting is listed in Table 2-I. The Ebert spectrometer was calibrated at 313 nm, 334 nm and 366 nm with a mercury lamp. The wavelengths used when describing the experiments are the positions of maximum intensity rather than the monochromator settings. A rough sketch of the spectral output of the Osram HBO-500 Watt lamp is shown in figure 2-3 along with the absorption spectrum of ketene. During the photolyses a Corning filter, number CS 7-54, was placed in front of the photolysis cell to prevent transmission of second order wavelengths from the monochromator and scattered visible light.

350 nm	347 nm	----

Figure 2-3 The Absorption Spectrum of Ketene from 200 nm to 400 nm
(Taken from Sauer, K. H., Ph.D. Thesis (Harvard University, 1957), p.128)

Photolyses in the 200 nm region were done using light from a Phillips, #93106E, 25 Watt, zinc lamp. The spectral output of the zinc lamp is sketched in figure 2-4 and compared to that found by Yamazaki and Cvetanovic³ in Table 2-II. A Baird-Atomic standard line filter for 214 nm with a full width of approximately 20 nm (courtesy of Professor W. A. Klemperer and Dr. Lynn Melton) was used to isolate the 214 nm region. Since very little light longer than 230 nm will be absorbed by ketene compared to the light absorbed in the 214 nm region, the filter does not have to have a narrow band pass in order to have a relatively narrow band of effective photolyzing light from the zinc lamp.

The Optical Arrangement for Photolysis

The optical train used with the Osram HBO-500 Watt lamp is shown schematically in figure 2-6. The Osram mercury lamp is virtually a point source lamp. The phototube used to monitor the light was an RCA 935-S5 vacuum diode with a 45 volt battery as the power supply.

The optical train was modified for the 214 nm photolyses. The monochromator and the Corning filter were removed and the Phillips zinc lamp, which is not a point source, was placed as close as possible to the photolysis cell (an asbestos housing

surrounding the photolysis cell was the limiting factor in positioning the lamp). The short focal length convex lens usually in front of the point source was placed in front of the lamp, and another convex lens replaced the first plano-convex lens and the interference filter was placed just before the cell. The RCA 935 phototube was replaced with a 1-P28 photomultiplier tube with a 300 volt DC power supply. The photomultiplier was connected to a Keithley 601 electrometer and the signal from the electrometer was monitored on the Hewlett-Packard recorder.

A suprasil photolysis cell, 15 cm long and 2 cm in diameter, was connected to a circulating pump which was operated continuously during the photolyses at 214 nm. At this wavelength, the extinction coefficient is so large that 90% of the light is absorbed within 0.65 cm of the front window of the cell. (This calculation assumes that the value of ϵ is 2.64×10^3 l/mole-cm, as given by T. A. Walter.⁴) Stirring is required to ensure that the reactions at 214 nm are not different from the reactions at the longer wavelengths because of local conditions, e.g., depletion of the ketene or extensive reactions of CH_2 with radicals in the volume right behind the front window.

4. Walter, T. A., Ph.D. Thesis (Harvard University, 1967)

TYPICAL OPTICAL ARRANGEMENT

Figure 2-6

Pressures in the photolysis cell were measured with a differential Wallace-Tiernan gauge (0-50 Torr) in conjunction with a standard mercury manometer. The polymer deposits on the windows of the photolysis cell were removed periodically with concentrated nitric acid and acetone. After each cleaning, the cell was seasoned by photolyzing ketene and a hydrocarbon (isobutane or cyclopropane) for one to two hours. A schematic of the gas handling line at the photolysis cell is shown in figure 2-7.

Beer's Law Studies and the Measurement of the Light Intensity

A Beer's Law series of absorption measurements in the pressure range of from 5 Torr to 50 Torr was done for each spectral region used. The experimental extinction coefficients and effective wavelengths are listed in Table 2-I. At 214 nm, even with 2.6 Torr of ketene, all of the incident light was absorbed. (Kistiakowsky and Walter⁵ Sauer,⁶ and Braun, Bass and Pilling⁷ all report an extinction coefficient greater than 1000 liters/mole-cm in this wavelength region.)

SCHEMATIC OF GAS HANDLING LINE AT THE PHOTOLYSIS CELL

Figure 2-7

Since absolute yields were to be determined, the amount of light absorbed during each photolysis was needed. The transmitted light was continuously monitored with either the RCA 935 phototube or the 1P-28 photomultiplier and was recorded with the Hewlett-Packard recorder during each photolysis. The power supply for the mercury lamp consisted of ten large lead batteries in the subbasement of the Mallinckrodt Laboratory. Since other members of the department used this power source, the input current of the mercury lamp varied during a typical photolysis and caused the light intensity to fluctuate. For this reason, the lamp's transmitted intensity was averaged over 15 minute intervals for the usual photolysis time of four hours. The amount of ketene decomposed (calculated by both CO yields and hydrocarbon yields) was never larger than 5% (usually 2-3%) so that the variation in the transmitted light was not due to changes in ketene concentration.

The changes in the intensity of the lamp could not be predicted and so the incident intensity during the photolysis was not well known and could not be used to calculate the light absorbed during the photolysis. Instead, the intensity of the light absorbed, I_a , was calculated from the intensity of the transmitted light, I_t , using Beer's Law,

$$I_a = I_t(10^{ec\ell} - 1.0),$$

where ϵ is the extinction coefficient in liters/mole-cm,
 c is the concentration of ketene in moles/liter,
and l is the length of the photolysis cell, 15.0 cm.

There are two major sources of error in the light measurements: errors of the measurement of the concentration of ketene and errors in the light intensity monitoring system. Generally, the concentration of ketene was known to better than 5%, and for small extinction coefficients, the error in I_a due to errors in the concentration of ketene will be small. In the wavelength region about 277 nm, the extinction coefficient, the intensity of the lamp output and the spectral response of the phototube were all small. Even with amplification, the intensity reading was never more than 20% of the full scale of the recorder. (The intensity readings for most other wavelengths were at least 50% of the full scale.) This small signal meant that the usual deadband error in the recorder (1.5% of the full scale) induced an error of approximately 10% in the light intensity measurements at 277 nm. Since the final product measurements were divided by the intensity of the absorbed light, large errors in the intensity were amplified in the product yields. This can be seen in the results (figures 3-3, 3-4, and 3-5) where the 277 nm yields have the largest random error. Estimating the position of the recorder tracing will result in a larger percentage of uncertainty in the smaller signals.

Since estimating the position of the recorder tracing depends on the operator's objectivity, there is a chance that the position will be consistently estimated either high or low. The error from the dead band of the recorder will also contribute to a consistently high or low reading.

At 214 nm, the ketene absorbs all of the light entering the photolysis cell. The Keithley electrometer and photomultiplier were used to monitor the transmitted light when no ketene was in the cell. (the incident light intensity) and the light scattered by the components of the optical train when ketene was in the cell. The transformer for the Phillips zinc lamp was an auto-leak transformer with a 140 Watt rating, and was operated from the line current (115 V, 60 Hz) had an open circuit voltage of 470 V.

Fortunately, the problem of fluctuating light intensity due to the power supply which complicated the experiments using the mercury lamp did not occur with the zinc lamp. The difference in intensity between the incident light and the scattered light (which was measurable and important only at this wavelength) was easily determined. There was very little difference between the incident light measured before and after each photolysis, and this was only a random difference. These two measurements were averaged and used for the incident light intensity.

The Purity of the Gases used in the Photolyses

The composition of the gas mixtures photolyzed in the isobutane experiments was 100 parts of isobutane, 10 parts of ketene, and 1 part of propane. The composition of the gas mixtures used in the cyclopropane experiments was 10 parts of cyclopropane and 1 part of ketene. Except for cyclopropane, the other hydrocarbons were Phillips Research Grade and were used without further purification. The cyclopropane was C.P. grade and its major impurity (and the only one detected on the gas chromatographic columns used) was 0.3% propylene. The propylene was used as an internal standard for gas chromatographic analysis and was measured before and after each photolysis.

Air Reduction Co. research grade O_2 was used in both the isobutane and cyclopropane experiments, and Air Reduction Co. research grade Xe was used in the isobutane experiments. According to the label, the Xe contained 120 ppm of Kr and less than 2.0 ppm of other impurities.

Matheson research grade CO was used in the isobutane experiments. Matheson lists the impurities as 4 ppm of O_2 , 960 ppm of N_2 , 15 ppm of Ar, 4 ppm of H_2 , and 45 ppm of CO_2 . To minimize the formation of $Fe(CO)_5$, a liquid with a measurable

vapor pressure at room temperature, the Matheson Company stores the research grade CO in a stainless steel tank. They seem to have forgotten that $\text{Ni}(\text{CO})_4$, a gas at room temperature, is formed more easily than $\text{Fe}(\text{CO})_5$ and the ease of formation is large for impure sources of nickel. The $\text{Ni}(\text{CO})_4$ present in the CO absorbed ultraviolet light (300 nm-350 nm) and produced some spurious results in the yields (because of light intensity measurements) until the cause was identified.

With Dr. John H. Marlow's help, the research grade CO from the tank was passed through a piece of pyrex tubing that was gently heated with a Bunsen burner, and a silver mirror, typical of Ni, was deposited at the cooler end of the tube.⁸ No metallic plating (or ultraviolet light absorption) was noticed in the C. P. grade CO. C. P. grade CO is stored in a standard steel tank, not in a stainless steel tank. Before use, the research grade CO was passed slowly from the tank through a coil packed with glass helices and immersed in liquid nitrogen and into a storage bulb. The $\text{Ni}(\text{CO})_4$, a white crystalline deposit which appeared on the helices just before the liquid nitrogen, was removed by this process. The gas which was stored did not show any absorption in the ultraviolet. No crystalline deposit was seen when C. P. grade

8. Walton, H. F., Inorganic Preparations, Prentice-Hall, Inc., (1948), pp. 93-96.

CO was passed through liquid nitrogen. Only research grade CO which was processed in this manner was used in the experiments. No C. P. grade CO was used.

Product Analysis

A Perkin-Elmer, model 154, Vapor Fractometer and accompanying flame-ionization detector were used to analyze the products. Helium was used as the carrier gas. Hydrogen and Air Zero (air with less than 2 ppm of hydrocarbons - expressed as methane) were used for the flame. A Leeds and Northrup Speedomax W recorder with a disc integrator was used to record the peaks and the integrated areas under the peaks. As will be discussed in the next section, the peak area was not measured solely by the disc integrator.

The sample injector system of the gas chromatograph was modified to allow the introduction of gas samples. A schematic of the injection system is shown in figure 2-8. An Aerograph (Type XA-204), 6-way linear valve with Viton o-rings was used to inject the samples. The samples were measured in the gas burette and then expanded into the coil. (See figure 2-8.) The volumes of the connecting tubing and coil were all known and so the exact fraction of the gas measured in the burette which

GAS CHROMATOGRAPHIC SAMPLE INLET SYSTEM

Figure 2-8

passed into the column was also known. One of the valve openings was sealed off so that when the coil was open to the rest of the tubing and the measured gas was let into the coil, the volume of gas not going into the gas chromatograph was a minimum. This dead volume was very small compared to the volume of the coil.

Neither the ketene nor any of the possible oxygen containing compounds (aldehydes, ketones, or alcohols) which might result from the reaction of O_2 and ketene or O_2 and butyl, cyclopropyl, or methyl radicals can be detected with the columns used. Presumably, they are so polar that they are retained on the columns and only gradually bleed off.

Part 1: The Product Analysis of the Isobutane System.

The column finally chosen to analyze the gases expected from the photolysis of the isobutane-ketene-propane mixtures (CH_4 , C_2H_4 , C_2H_6 , C_3H_8 , C_4H_8 , C_4H_{10} , C_5H_{12} , and C_3H_{18}) was a $\frac{1}{4}$ inch O.D. copper tube 6 m long, packed with 80/100 mesh Porasil C (Waters Associates). The column was crudely temperature programmed in order to elute the octanes before the peaks were too broad to be measurable and within a reasonable analysis time. (At least two analyses were done for each photolysis.) The temperature was set at $70^\circ C$ until the pentanes were off the column, after which the temperature was reset at $110^\circ C$ until the octanes

had eluted. A Perkin-Elmer Column E was used for those experiments in which isobutene was also monitored.

The Porasil C column was chosen because the tailing from the comparatively huge amount of isobutane was small (although as seen from figure 2-9a, the tailing was still significant), the octanes could be measured on the same column with almost all of the major products, and the two largest products (neopentane and isopentane) were well resolved, not too broad, and distinct from the isobutane. Figure 2-9a shows a typical chromatogram (shortened to include the octanes). The isobutene came off within the isobutane tailing on the Porasil C column and was hidden by it, and so for some experiments, the photolyzed gas mixture was also analyzed with a Perkin-Elmer Column E. However, neopentane was only barely distinct from the isobutane on Column E, and as seen in figure 2-9b, the neopentane's base line was much too steep for accurate measurements of the peak area.

The area under a peak is proportional to the amount of gas represented by the peak. Propane was used to calibrate the response of the detector. The calibration is shown in figure 2-10; the peak area increases linearly with an increase in sample size. When detected by flame ionization, the peaks are also proportional to the number of carbons in the hydrocarbon. Ettre⁹ has tabulated

9. Ettre, L. S., "Relative Molar Response of Hydrocarbons on the Ionization Detectors," in Gas Chromatography, Brenner, N., Callen, J. E., and Weiss, M. D., eds. (Academic Press, New York, 1962).

with Propane

Figure 2-10

the response of various hydrocarbons relative to n-heptane (700). A small portion of his table is repeated in Table 2-III for those alkanes studied in this work. Ettre did not list any olefins and so the olefin responses were estimated to be the same as the corresponding alkane, e.g., isobutene's response was set equal to the isobutane and n-butane response of 378.

Although the detector response increases linearly with increasing sample size, the use of an internal standard is preferred when measuring absolute yields. An internal standard eliminates errors due to errors in measuring the sample size and also serves as a check on the concentration of the hydrocarbons in the unphotolyzed reaction mixture. There was also an additional advantage to using an internal standard with this detector. Each time the detector cap was removed there was a chance that the platinum collecting electrode would be disturbed. Any displacement of the collecting electrode would change the geometry of the electric field and thus the response of the detector. The hydrogen flame was lit manually which required removing and then replacing the detector cap. This was done each day the gas chromatograph was used in order to minimize heat fatigue in the leads within the detector block.

The recorder used with the gas chromatograph was equipped

TABLE 2-III

The Molar Response of the Hydrocarbons with a Flame Ionization Detector

Hydrocarbon	Ettre's Relative Molar Response	Response Used
Methane	90	90
Ethane	189	189
Propane	284	284
Isobutane	378	378
n-Butane	378	378
Neopentane	---	525
Isopentane	529	525
n-Pentane	524	---
2,5Dimethylhexane	806	800
2,2,4 Trimethylpentane	798	800
2,2,4,4 Tetramethylbutane	---	800

with a disc integrator. The disc integrator is the most accurate of the methods used to measure peak areas, but only when the base line is straight. The disc integrator was used to measure the earlier peaks, methane, ethane, and propane. The isobutene and pentanes appear on the tail of the isobutane and since the base line has a considerable curvature to it, the disc integration method is not suitable. The base lines were estimated using a French curve (the dotted lines in figure 2-9a). At least two and usually four planimeter tracings were made of each peak. Several different sizes of propane peaks were measured using both methods, disc integration and planimeter tracings. These were used to relate the two methods so that direct comparisons between all the peaks could be made.

A third method of measuring the peak areas was tried. The chromatograms were xeroxed and the peaks were cut out and weighed on a much abused Mettler analytical balance. This method should have been more precise than the planimeter tracings. However, since continuous calibration of the balance would have been necessary to achieve this precision, this method was abandoned in favor of the planimeter method, a much less time consuming method.

The error in measurements from the planimeter method was on

the order of 2-3% for the larger peaks and as much as 10% for the smaller peaks. (At least four planimeter tracings were made for the smaller peaks.) The error in peak areas as measured by the disc integrator was 2-3%.

Part 2: The Product Analysis of the Cyclopropane System

The products expected from the photolysis of ketene and cyclopropane are methylcyclopropane, isobutene, butene-1, and cis- and trans- butene-2. Ideally, the separation of all five isomers is required. The minimal acceptable separation is the separation of the methylcyclopropane from the butenes and the separation of the butenes from the reactants so that the life-times of the methylcyclopropane can be measured. Several columns were tried and rejected for various reasons.

The first column tried was the Perkin-Elmer Column E (a 30 foot long, 1/8 inch O.D. stainless steel tubing packed with 33% dimethylsulfolane on 60/80 mesh Chromosorb P) operated at 30°C and a flow rate of 6 cm³/minute. The isobutene and butene-1 peaks were hidden under the very large cyclopropane peak, and the trans-butene-2 was not separated from the methylcyclopropane. The second type of column tried was a silver nitrate-ethylene glycol (or carbitol) column. Several of these columns were made and tried. The columns had to be operated in an ice bath because

the Ag-olefin complexes which determine the order of elution are destroyed near room temperature. But even in an ice bath, the columns had an unusually large background noise. The butene-1 came off with the cyclopropane and so could not be measured. The remaining peaks were fairly well resolved, but the noisy background would have prevented any meaningful quantitative analysis.

M. Papić¹⁰ claimed to have separated the C_4 's on a Porapak Q column. The column eventually used was a piece of 10 foot long, $\frac{1}{4}$ inch O.D. copper tubing filled with 2 parts of Porapak Q and 1 part of Porapak Q-S (both 50/80 mesh). (The Porapak Q-S is the same as the Porapak Q, but is treated with silane in order to reduce tailing.) The 50/80 mesh Porapak Q separated the products much better than the 80/100 mesh recommended by Papić, and there was no significant peak distortion as claimed by Papić. Although the products (with the exception of the last peak, the cis-butene-2 peak) were not completely resolved from each other, the resolution was the best of the columns tried. The isobutene and butene-1 were not resolved from each other. One of the biggest advantages of this column was that by the time the C_4H_8 products were eluted from the column, there was no tailing from the cyclopropane.

10. Papić, M., J. Gas Chromatography 6, 493 (1968).

A typical chromatogram is shown in figure 2-11. The methane, ethane, ethylene and propylene (unresolved from each other), and cyclopropane are not shown in the figure. Dotted lines show the estimate made for resolution. This lack of resolution introduced the largest error in the yield of methylcyclopropane relative to the olefins for small photolysis pressures where the yield of methylcyclopropane compared to the olefins was smallest. Under these conditions, more than 20% of the methylcyclopropane peak will be under the two side peaks (isobutene and butene-1 and trans-butene-2, figure 2-11).

The error from estimating the shape of the methylcyclopropane when the peaks of the butene isomers were a significant percentage of the products was minimized by comparing the methylcyclopropane peaks with a set of different sized peaks of methylcyclopropane. This set was constructed from the gas chromatographic analysis of 690 Torr of a mixture of 20:1:1, cyclopropane to ketene to oxygen, photolyzed at 313 nm. At this pressure, close to 90% of the total C_4H_8 products was methylcyclopropane. Five different sample sizes of the products were analyzed, and these chromatograms were used as a guide in estimating the shape of the edges of the methylcyclopropane peak in the other photolysis mixtures. At least two planimeter tracings were made for each peak. This method seemed to work fairly well, since the butene to methylcyclopropane ratio for two different sized samples from the same

methlycyclopropane
Porapak Q and QS-50/80 mesh
t=80°C, flow rate=100cc/min.

Elution time in minutes

Figure 2-11

photolyzed mixture generally agreed to within 6%.

The molar responses of all the C_4H_8 isomers was assumed to be the same. Cis- and trans- butene-2 are known to have the same molar response.¹¹ According to Ettre,⁹ both n-butane and isobutane have the same molar response and the response for the two different pentanes differs by less than 1%. In light of these facts, the assumption of equal molar responses for all C_4H_8 isomers is reasonable.

The Procedure for a Typical Experiment

A standard vacuum line with teflon stopcocks or stainless steel valves where the the stopcocks might come in contact with the photolyzed gases was used for handling and measuring the gases. Before each photolysis and before making up any gas mixture, the system was pumped down to 10^{-5} Torr with a mercury diffusion pump, liquid nitrogen trap, and mechanical pump. Each of the stored gases, ketene, isobutane, propane, and cyclopropane, was thoroughly out-gassed by pumping on the frozen sample during two freeze-thaw cycles before it was used.

The gases were measured with the Wallace-Tiernan gauge and

11. Anderson, E. M., Ph. D. Thesis (Harvard University, 1968).

mercury manometer and were stored and mixed in a bulb which was taped and painted black in order to prevent any reaction caused by the room lights. The ketene mixture was never used after more than five days of storage because too much of the ketene would have been polymerized and the concentration of ketene in the mixture would have been in error. Periodically, a brown polymer coating on the teflon stirrer and the sides of the flask was removed with acetone. The extent of mixing was checked by light absorption measurements which showed that three hours of mixing was sufficient to completely mix the gases.

If oxygen was to be added to the ketene-isobutane mixture, the oxygen was slowly introduced into the cell and then the mixture was added slowly with the circulating pump on to stir the gases. The entire mixture was mixed in the cell for 1.5 hours before photolysis. In the earlier experiments with oxygen, the ketene-isobutane mixture was added first and then frozen out with liquid nitrogen. The oxygen was added and measured while the mixture was frozen. After the oxygen was added, hot water was used to quickly vaporize and mix the ketene and isobutane with the oxygen. The circulating pump then mixed all of the gases for 1.5 hours before photolysis. This procedure gave spurious results for the oxygen experiments; the yield of isopentane seemed to be larger than in those experiments which had no oxygen. The

explanation is that the sudden increase in gas pressure forced the oxygen into the dead space connecting the Wallace-Tiernan gauge to the cell. There was no difference if the CO was added before or after the ketene-isobutane mixture (with or without freezing the ketene and hydrocarbons). In the cyclopropane experiments, the oxygen was added to the mixture as it was made up and stored in the flask. In most of the isobutane experiments, the stirring was continued during the photolysis.

The lamp to be used was allowed to warm up and stabilize for 30 to 60 minutes before photolysis. The Phillips zinc lamp needs 30 minutes for the light intensity at 214 nm to stabilize, although visually, 10-15 minutes were enough for the blue and red lights to be stabilized. The Osram mercury lamp needed 45-60 minutes to stabilize.

After photolysis, the product mixture was connected to a trap filled with glass beads and helices and immersed in nitrogen slush for 30 minutes. The nitrogen slush was made by pumping a vacuum on a dewar of liquid nitrogen for at least 30 minutes. Then the non-condensable contents of the cell were Toepler-pumped into a gas burette and storage bulb. If no gases had been added to the ketene-hydrocarbon mixture, the CO yield was measured in the gas burette. Typically this was about 1 μ mole of gas. The yield of non-condensables was not measured when CO or O₂ was added.

because it would have been impossible to see any change, even in the oxygen experiments.

The condensed fraction was transferred to a sampling bulb by heating the trap with hot water and freezing the gases in the sampling bulb. Each sampling bulb had a teflon stopcock and contained 4 glass beads for stirring. In order to ensure a complete transfer of gases, the transferring process was given 30 minutes. After the sample bulb was removed, it was dipped into hot water and stirred vigorously for 5 minutes. The sampling bulb was then attached to the inlet system for the gas chromatograph.

Differences Between the Light Intensity Measurements at

214 nm and the Longer Wavelengths.

The quantum yield for ketene decomposition at 214 nm has been estimated by Walter and Kistiakowsky.⁵ They found the CO quantum yield over a pressure range of 2-50 Torr to be between 2.2 and 2.5. Because of the errors involved in making the comparison with the ammonia actinometer, this yield can be rounded off to 2. (A quantum yield of 2.0 means the quantum yield for the decomposition of ketene is 1.0.) The quantum yield of CO at wavelengths shorter than 290 nm has been measured by several

workers¹² who all agree that it is 2.0 ± 0.2 .

Since the optical arrangements at 214 nm were so different from the arrangements at the other wavelengths, it was necessary to relate the light intensity measurements at 214 nm with those at the other wavelengths. At first, 5 Torr of ketene were photolyzed at 214 nm and at 277 nm and both the CO and C₂ hydrocarbon yields were measured. The quantum yield of the CO (or for ketene decomposition) at both wavelengths will be directly proportional to the light absorbed and to the photolysis time. A sample of the ketene used for each photolysis was analyzed on the gas chromatograph and any ethylene measured was subtracted from the product analysis of the photolyzed ketene. In order to be sure the geometry of the electrical field did not change, the flame of the analyzer in the chromatograph was not relit during these experiments. The peak areas per μ mole of sample for ethylene, ethane, and acetylene were measured. The comparison between quantum yields of CO at both wavelengths was not very satisfactory because the CO yield was too small to be accurately measured in the gas burette. A conversion factor used to relate the light intensities at the two wavelengths was calculated using the CO yields and

12. DeGraff, B. A. and Kistiakowsky, G. B., J. Phys. Chem. 71, 1553, 3984 (1967); Strachan, A. N. and Noyes, W. A., Jr., J. Am. Chem. Soc. 76, 3258 (1954); Cox, R. A. and Preston, K. F., Can. J. Chem. 47, 3345 (1969).

also using the C_2 hydrocarbon yields. The conversion factor calculated from these two different product yields differed by more than 50%, and so a new method was tried.

When 50 Torr of isobutane and 5 Torr of ketene were photolyzed at both 313 nm and 277 nm, the quantum yields were equal. (See the chapter of isobutane results, chapter 3.) The measurements of the yields at 313 nm in our system were more accurate than at 277 nm, and so long as the quantum yields are the same at both wavelengths, photolyses at 313 nm are preferred for comparisons with other wavelengths. A comparison of the yields of the photolyses of 50 Torr of isobutane and 5 Torr of ketene at 313 nm and 214 nm gives a conversion factor which relates the two different light intensities and which is very close to the one calculated using the CO yields from the photolyses of ketene at 277 nm and 214 nm discussed above. It has been assumed, of course, that the quantum yields for ketene decomposition are the same at both wavelengths. The decomposition of ketene at 214 nm is pressure independent⁵, so the addition of 50 Torr of isobutane should not change the quantum yield for the decomposition of ketene. A comparison of yields is only necessary for the isobutane experiments, and the fact that the quantum yield for ketene decomposition at 214 nm is not known with great certainty is not important as will be discussed in chapter 4.

Results of the Photolysis of the Ketene-Isobutane System

General Trends

Neopentane and isopentane are the major products¹ of the photolysis of a mixture of isobutane, ketene, and propane (in a ratio of 100:10:1). The other significant products are isobutene and the two octanes, 2,2,3,3-tetramethylbutane (octane B) and 2,2,4-trimethylpentane (octane A). The yields of these products are compared for photolyses done at different wavelengths in Table 3-I. Figure 3-1b shows the increase in the ratio of neopentane to isopentane product yields as the photolyzing wavelength increases. In these tables and figures, unless otherwise specified, the yield of a product refers to its yield relative to propane and has been normalized to a standard time and number of photons absorbed.

The photolyzing wavelengths used were 214 nm, 277 nm, 313 nm and 330 nm. Some experiments were tried at 350 nm and 366 nm, but since here the extinction coefficient of ketene is small and the quantum yield decreases to very small values (e.g., 0.01 at 366 nm

1. "Products" refers to only the products condensable in liquid nitrogen unless stated otherwise. CO is, of course, a major product, too, but it is not condensable and was not always measured.

and 50 Torr of ketene),^{2,3,4,5} the product yields even after a twenty hour photolysis were too small to be measurable.

In some experiments, oxygen (5-10% of the total pressure) was added to the reaction mixture in order to eliminate the reactions of $^3\text{CH}_2$ with isobutane (or ketene). (See Chapter 1, Introduction.) As shown in Tables 3-I, 3-II and 3-III and in figures 3-3, 3-4 and 3-5, the neopentane and isopentane yields were all smaller in those experiments with oxygen than in those without oxygen. The addition of oxygen completely eliminated the isobutene and octanes which are expected when $^3\text{CH}_2$ reacts with isobutane. (See page 4 in Chapter 1.) The ratio of neopentane to isopentane in the oxygen experiments was less than in the experiments without oxygen and was between 0.14 and 0.15 regardless of the photolyzing wavelength (see Table 3-II). This agrees well with the results of several other workers.^{6,7}

Neopentane and isopentane are products of the reactions of isobutane and both $^1\text{CH}_2$ and $^3\text{CH}_2$. The reaction of $^1\text{CH}_2$ with isobutane is a concerted reaction in which the $^1\text{CH}_2$ inserts almost statistically into the C-H bonds of isobutane. Thus, the ratio of neopentane to isopentane expected when only $^1\text{CH}_2$ reacts with isobutane is close to 1/9 or 0.11. The reaction of $^3\text{CH}_2$ with C-H bonds is a two step reaction. In the first step, $^3\text{CH}_2$ abstracts a H from a C-H bond thus forming an alkyl radical and a methyl radical. And in the second step, the alkyl and methyl radicals recombine. $^3\text{CH}_2$ abstracts a tertiary H in preference to a secondary H and a secondary H in preference to a primary H. This order of preference is predicted by the order of stability of the resulting alkyl radicals, i.e., the tertiary alkyl radical is the most stable. Thus, the reaction of $^3\text{CH}_2$ with isobutane favors the formation of neopentane rather than isopentane, and when $^3\text{CH}_2$ reacts with isobutane, the ratio of neopentane to isopentane is expected to be larger than when only $^1\text{CH}_2$ reacts with isobutane.^{8,9} The addition of oxygen prevents the reaction of $^3\text{CH}_2$ with isobutane and the yields of both pentanes and the neopentane / isopentane ratio are expected to be smaller than when no oxygen has been added.

8. See the review articles: Frey, H. M., *Prog. React. Kinet.*, 2, 131 (1964); Bell, J. A., *Prog. Phys. Org. Chem.* 2, 1 (1964); DeMore, W. B. and Benson, S. W., *Adv. Photochem.* 2, 219 (1964).

9. Dobson, R. C., Hayes, D. M., and Hoffmann, R., *J. Am. Chem. Soc.* 93, 6188 (1971).

The ratio of neopentane to isopentane increases as the percentage of $^3\text{CH}_2$ increases. Thus, figure 3-1b shows, as expected from other work, that the percentage of $^3\text{CH}_2$ increases as the wavelength of the photolyzing light increases.^{10,11,12,13}

CO was also added to the photolysis mixture in some experiments. As expected from previous work,^{11,14} the addition of CO results in a decrease in the yields of the products from the reactions of both $^1\text{CH}_2$ and $^3\text{CH}_2$ with isobutane. (See Table 3-II and figures 3-3, 3-4 and 3-5.) When more than 60 Torr of CO has been added to the photolysis mixture, the ratio of neopentane to isopentane is the same as in the oxygen experiments (see Table 3-II) and no isobutene or octanes are present.

In two experiments at 277 nm and 313 nm, xenon was added to the photolysis mixture. In the presence of added "inert" gases.

the amount of $^3\text{CH}_2$ present is expected to increase.^{15,16,17,18,19} As anticipated, the yields of the products of the $^3\text{CH}_2$ reaction with isobutane (i.e., the neopentane to isopentane ratio, neopentane, isobutene, and the octanes) increased in the xenon experiments as compared to the experiments in which no xenon was added. The yields are shown in Tables 3-I and 3-III.

The details of these experimental results are discussed in more detail in the rest of this chapter and in conjunction with the reactions listed in Table 3-IV which, on the basis of previous work,^{12,20} are expected in the ketene-isobutane system.

} Radical
Recombination

Notes: Oct-C (2,5 dimethylhexane) was not observed and so reaction k_8 is negligible.

IsoB, IsoP and NeoP refer to isobutane, isopentane and neopentane, respectively.

The Ketene-Isobutane Photolysis System

In addition to neopentane, isopentane, isobutene and the two octanes, 2,2,3,3-tetramethylbutane and 2,2,4-trimethylpentane, the photolysis of a mixture of ketene and isobutane also results in the formation of methane, ethane, ethylene, a small amount of hexanes, and carbon monoxide. The hexanes, secondary reaction products, are expected from the reactions of methylene with the pentanes. Since only a few percent of the ketene were decomposed during each photolysis, the amount of hexanes formed was too small to be measured. The methane was not monitored closely because it has a measurable vapor pressure, 0.3 Torr at -210°C , the nitrogen slush temperature, and some of it was always pumped by the Toepler pump into the non-condensable fraction along with CO. In all cases, the amount of methane remaining in the condensable fraction was smaller than the ethane yield. Ethylene was eluted from both the Porasil C column and the Perkin-Elmer Column E too close to the propane, which was at least 100 times larger than the ethylene, to be measurable. By comparisons with earlier qualitative experiments performed by Dr. Benjamin DeGraff, the amount of ethylene was estimated to be on the order of 5-8% of the total yield.

Ethane, a $^3\text{CH}_2$ product, was measured when neither CO nor O_2 were added. At most wavelengths, ethane was only 5-9% of the

of the total condensable products. The "total quantum yield", defined on p.76, is the yield of products from the reactions of both methylenes with isobutane and was used as an estimate of the total amount of CH_2 produced during the photolysis of ketene. Ethane results from the reaction of $^3\text{CH}_2$ with both ketene and isobutane²¹. Although the extent of the reaction of $^3\text{CH}_2$ with ketene was small (see Chapter 4), the yields of the isobutene and the two octanes were more easily measured, were free from the contribution of the ketene reaction, and were used in preference to the ethane yields. (See, also, Appendix I which estimates some of the steady-state concentrations of the radicals in the ketene-isobutane system).

The neopentane to isopentane ratio increases as the wavelength of the photolyzing light increases which, as mentioned above, indicates that the percent of $^3\text{CH}_2$ in the methylene is increasing. There is a sharp rise in the neopentane to isopentane ratio at wavelengths longer than about 320 nm. This sharp increase occurs at the same wavelength that the ratio of the yields of ethylene in a pure ketene system to the ethylene in a ketene-oxygen system sharply increases.¹¹ Both indicate that at wavelengths longer than 320 nm, the ratio of products from $^3\text{CH}_2$ reactions to those from $^1\text{CH}_2$ reactions suddenly increases. This correlation is shown in

21. See, for example, Frey, H.M. and Walsh, R., J. Chem. Soc. A 1970, 2115 for a discussion of the reactions of $^3\text{CH}_2$ with ketene.

figure 3-1. The reasons for this increase are discussed in Chapter 4.

The ratio of isobutene to octane B is 4.5 for all wavelengths. (see Table 3-III). By reactions (6) and (9)

$$\frac{d[\text{OctB}]}{dt} = k_6 [\text{t-C}_4\text{H}_9\cdot]^2 = R_{\text{OctB}}$$

and

$$\frac{d[\text{isobutene}]}{dt} = k_9 [\text{t-C}_4\text{H}_9\cdot]^2 = R_{\text{isobutene}}$$

so that

$$\frac{[\text{isobutene}]}{[\text{OctB}]} = \frac{k_9}{k_6} = 4.5. \text{ This agrees excellently with the}$$

value of 4.59 found by Kraus and Calvert²² in their work with di-t-butylacetone. Ring and Rabinovitch²³ used a value of 2.20 for the ratio of k_9/k_6 . Calculations described in Appendix I confirmed that the reaction

was a negligible source of isobutene. This was to be expected since CH_4 was such a small part of the products.

In order to compare the yields at various wavelengths, the

22. Kraus, J. W. and Calvert, J. G., J. Am. Chem. Soc. 79, 5921 (1957).

23. Ring, D. F. and Rabinovitch, B. S., Can. J. Chem. 46, 2435 (1968).

rate of formation of the products was needed for each wavelength. The rate of formation of CO was measured at several wavelengths and was normalized to a standard amount of absorbed light. This is referred to in the following pages as the yield of CO. According to the list of reactions given in Table 3-IV, if the reactions of both methylenes with ketene are minor compared to their reactions with isobutane, there is one molecule of CO formed for every CH₂ formed.

Unfortunately, because of the low percentage conversion of ketene, the CO yield was too small to measure accurately in those experiments where the extinction coefficient of ketene was very small. An alternative method for calculating the yields is to equate the yield of the products of the butyl radical reaction and the pentanes with the number of CH₂ radicals formed. Thus,

$$\begin{aligned} R_{\text{Total}} &= R_{\text{C}_5\text{H}_{12}} + 2 R_{\text{isobutene}} + 2 R_{\text{OctA}} + 2 R_{\text{OctB}} \\ &= R(^1\text{CH}_2) + R(^3\text{CH}_2). \end{aligned} \quad (\text{Eq. 1})$$

By reaction (9), one molecule each of isobutene and isobutane is formed from two butyl radicals, but since the amount of isobutane formed cannot be measured, twice the amount of isobutene is used in Eq.1. For those wavelengths where a good measurement of CO was obtained, the yield of CO was, as expected, equal to the total yield (normalized to a standard amount of absorbed light) of C₄, C₅ and C₈ products. (See Table 3-III, where both the CO yield and the total yields are listed for a series of 313 nm

photolyses.) The total yield of C_4 , C_5 and C_8 products will be referred to as the total quantum yield, R_{Total} .

The total quantum yield at 313 nm was found to be equal to that at 277 nm. The total quantum yield at 330 nm is 0.58 of that at 277 nm and 313 nm. Since the quantum yield of CO from the photolysis of ketene at 214 nm was reported as approximately 2.2²⁴ and the quantum yield of CO at 313 nm and 277 nm is 2.0,²⁻⁵ the total quantum yield at 214 nm was set equal to the yield at 277 nm and 313 nm. This point will be explored in more detail in Chapter 4.

Table 3-III presents the results of a series of experiments, at 313 nm, in which the yields obtained with the standard mixture (50 Torr of isobutane, 5 Torr of ketene, and 0.5 Torr of propane) are compared to the yields resulting from variations in the mixture. The most important observation is that the total quantum yield, R_{Total} , did not change when the isobutane pressure was doubled, when the total pressure of the mixture was doubled, or when xenon was added to the mixture. A second important observation is that the ratio of the neopentane to isopentane yields does not change when the pressure of isobutane is doubled or when the total pressure of the mixture is doubled. In Chapter 4 we will discuss why these

24. Kistiakowsky, G. B. and Walter, T. A., J. Phys. Chem. 72, 3952 (1968).

two observations justify the assumption that, for these ratios of ketene and isobutane, the reaction of $^3\text{CH}_2$ with ketene is minor compared to the reaction with isobutane. The observation that the ratio of neopentane to isopentane does not change when the total pressure is doubled indicates that the intersystem crossing which is responsible for part of the formation of $^3\text{CH}_2$ occurs from $^1\text{CH}_2$ rather than in ketene. This, too, will be explained in the next chapter.

The Ketene-Isobutane- O_2 Photolysis System

The addition of 2-5 Torr of O_2 to the standard reaction mixture eliminated the products which are usually attributed to radical recombinations, i.e., methane, ethane, isobutene, and the octanes. The remaining products are neopentane and isopentane (and some ethylene). The yields of both neopentane and isopentane were smaller than in the systems without oxygen.

The ratio of neopentane to isopentane in the presence of O_2 was 0.14-0.15 for all wavelengths and did not vary with the amount of isobutane or with the total pressure. This is in excellent agreement with the values found by other workers using several different sources of methylene,^{6,7} but is in striking disagreement with Ring and Rabinovitch.²³ (They found a value of 0.5 in their diazomethane-oxygen system.)

The Reaction of Oxygen with $^1\text{CH}_2$

Since O_2 is known to react very quickly with $^3\text{CH}_2$ ²⁵ and radicals²⁶ but not with $^1\text{CH}_2$, the addition of O_2 should eliminate the products of the reaction of $^3\text{CH}_2$ with isobutane. While Carr¹⁵ finds that $^1\text{CH}_2$ does react with O_2 and that this rate constant depends on the photolyzing wavelength of the ketene, the possibility of the reaction of an excited ketene molecule with oxygen is not excluded in Carr's experiments. Bell also measured the reaction of $^1\text{CH}_2$ with O_2 ²⁰ and using his values for the rate, the reaction is slow enough to be negligible when oxygen is only a few percent of the total reactants. Dhingra and Koob also assume the reaction of O_2 with $^1\text{CH}_2$ is negligible when oxygen is not present in large amounts.²⁷ If the ratio of the rate constants for the $^1\text{CH}_2$ reaction with O_2 compared to the $^1\text{CH}_2$ insertion into isobutane is 0.5, the largest of Carr's ratios, the $^1\text{CH}_2$ reaction with O_2 would be 2% of the reaction with isobutane since the ratio of isobutane to oxygen in our experiments was 50 to 2. This point will be more thoroughly explored in Chapter 4.

Two photolyses were done at 313 nm, one with 0.6 Torr of O_2

-
25. Russell, R. L. and Rowland, F. W., J. Am. Chem. Soc. 90, 1671 (1968).
26. van der Bergh, H. E. and Callear, A. B., Trans. Faraday Soc. 67, 2017 (1971).
27. Dhingra, A. K. and Koob, R. D., J. Phys. Chem. 74, 4490 (1970).

and one with 4.8 Torr of O_2 added to the standard mixture. There was no difference either in the neopentane to isopentane ratio or in the pentane yields between the two photolyses. Most of the other wavelengths were studied with both 2 Torr and 5 Torr of O_2 added and within experimental error, no difference was observed in the pentane yields. This again demonstrates the unimportance of the reaction of 1CH_2 with oxygen in these experiments and only the average values obtained in the O_2 experiments are reported in the final results.

The Determination of the Percent of 3CH_2 Present in the Ketene-
Isobutane System

The ratio of the total quantum yield of a mixture photolyzed with O_2 to the total quantum yield in the absence of O_2 is a measure of the fraction of methylene present as 1CH_2 in the system. Since the total quantum yield is due only to methylene, and on assuming that there are only two forms of methylene, 1CH_2 and 3CH_2 , the percentage of 3CH_2 becomes equal to (100- the percentage of 1CH_2 as just defined). The percentage of 3CH_2 measured by this method is referred to as $^3CH_2\% - O_2$ to distinguish it from the percentage of 3CH_2 measured by other methods. The reaction of 1CH_2 with O_2 has thus been ignored. Inclusion of this reaction would only slightly enhance the percentage of 3CH_2 measured in the oxygen experiments. The change in $^3CH_2\% - O_2$ with wavelength

is shown in figure 3-1a. The variation in $^3\text{CH}_2\text{\%}-\text{O}_2$ parallels the variation in the neopentane to isopentane ratio.

The neopentane to isopentane ratio increases as the percentage of $^3\text{CH}_2$ present increases. The relationship between the neopentane to isopentane ratio and the $^3\text{CH}_2\text{\%}-\text{O}_2$ is shown in figure 3-2. A point was added to show the value of the ratio expected when only $^1\text{CH}_2$ reacts with isobutane to form the pentanes i.e., when O_2 has been added. The neopentane to isopentane ratio can be expressed as a function of the percent of $^3\text{CH}_2$ and of $^1\text{CH}_2$,

$$\frac{\text{NeoP}}{\text{IsoP}} = {}^1\text{CH}_2\% \left[\frac{\text{NeoP}}{\text{IsoP}} \right]_S + {}^3\text{CH}_2\% \left[\frac{\text{NeoP}}{\text{IsoP}} \right]_T \quad (\text{Eq. 2})$$

$\left[\frac{\text{NeoP}}{\text{IsoP}} \right]_S$ is the ratio expected when only $^1\text{CH}_2$ is present, i.e., the ratio in the presence of oxygen, 0.14-0.15, and $\left[\frac{\text{NeoP}}{\text{IsoP}} \right]_T$ is the ratio expected when only $^3\text{CH}_2$ is present. In Eq. 2, it is assumed that all of the methylene reacts with isobutane to form pentane products, or, in other words, that ${}^1\text{CH}_2\% + {}^3\text{CH}_2\% = 100$. As can be seen from Table 3-I, only 30% of the products of the $^3\text{CH}_2$ reactions with isobutane are the pentanes. The rest of the products of these reactions are the other radical recombination products, namely isobutene (and isobutane) and octanes. All of the $^1\text{CH}_2$ reacts with isobutane to form pentanes. If the neopentane to isopentane ratio is expressed as a function of $^3\text{CH}_2$, Eq. 2 becomes

$$\frac{\text{NeoP}}{\text{IsoP}} = \left[\frac{\text{NeoP}}{\text{IsoP}} \right]_S + {}^3\text{CH}_2\% \left\{ 0.30 \left[\frac{\text{NeoP}}{\text{IsoP}} \right]_T - \left[\frac{\text{NeoP}}{\text{IsoP}} \right]_S \right\} \quad (\text{Eq. 2a})$$

Since the intercept of the line in figure 3-2 is not 0.14-0.15, the knowledge of the ratio of neopentane to isopentane when less than 36% of the methylene present is $^3\text{CH}_2$ would have been useful. However, when the reaction with isobutane is the main reaction in a methylene system, and no $^3\text{CH}_2$ scavengers are present, there will never be less than approximately 36% $^3\text{CH}_2$. This last point will be explained in Chapter 4.

Doubling the total pressure of the standard reaction mixture which also contains 4% oxygen does not change either the neopentane to isopentane ratio, the total quantum yield, or the $^3\text{CH}_2\text{-O}_2$ at 313 nm (see Table 3-III). Also, doubling the amount of isobutane in the oxygen experiments does not change either the ratio of yields of neopentane to isopentane, or the total quantum yield, or the $^3\text{CH}_2\text{-O}_2$ at 313 nm. As will be explained in more detail later, this justifies the assumption that the reaction of $^1\text{CH}_2$ with ketene is negligible compared to its reaction with isobutane.

The Ketene-Isobutane-CO Photolysis System

The products attributed to the reactions of $^3\text{CH}_2$ are suppressed when CO is added to the standard photolysis mixture. At all wavelengths, the presence of 60 Torr of CO is sufficient to reduce the ratio of neopentane to isopentane to 0.14-0.15, the value observed in the presence of oxygen, and to completely

suppress the ethane, isobutene, and octanes yields. This is shown in Table 3-II. The decrease in pentane yields at the different wavelengths as the pressure of CO is increased is also shown in this table and in figures 3-3, 3-4 and 3-5.

In some early experiments done at 313 nm, 0.5 Torr of O₂ and 25 to 150 Torr of N₂ were added to the standard ketene-isobutane-propane mixture. Only the pentane products were monitored, and the quantum yields of the pentanes were not determined very accurately, but they were definitely smaller in the presence of O₂ and N₂ than in the presence of only N₂ or in the absence of both N₂ and O₂. Unfortunately, the data are not good enough to determine the extent of the reaction of ¹CH₂ with N₂. In the presence of N₂ and O₂, the neopentane to isopentane ratio was 0.14-0.15 independent of the pressure of the N₂. These experiments were done to be sure that the ratio of neopentane to isopentane due to only ¹CH₂ did not change with the addition of large amounts of less reactive, diluent gases, e.g., CO.

In the presence of more than 60 Torr of CO, all of the ³CH₂ reacts with CO as judged from the composition of the products. When the ratio of CO to isobutane is larger than 1.2, the reaction of ³CH₂ with isobutane is not fast enough to compete with the reaction of ³CH₂ with CO. Both ¹CH₂ and ³CH₂ react with CO to form ketene (reactions 13 and 14 below). However, in the concentrations

of CO used in this study, most of the $^1\text{CH}_2$ reacts with isobutane and not with CO. (Thus, for $^1\text{CH}_2$, $(k_1 + k_2) [\text{IsoB}] > k_{13} [\text{CO}]$, but for $^3\text{CH}_2$, $(k_4 + k_5) [\text{IsoB}] < k_{14} [\text{CO}]$.)

When the CO concentration is large enough to suppress the reaction of $^3\text{CH}_2$ with isobutane, the pentanes are the only products observed (aside from a trace of C_2H_4), and assuming steady state conditions for the radicals, the rate of formation of isopentane is given by

$$\frac{d}{dt} \text{IsoP} = \frac{k_1 [\text{IsoB}] \phi_s I_a}{(k_1 + k_2) [\text{IsoB}] + k_{13} [\text{CO}]} = R_{\text{IsoP}} \quad (\text{Eq. 3})$$

and the rate of formation of neopentane is given by

$$\frac{d}{dt} \text{Neop} = \frac{k_2 [\text{IsoB}] \phi_s I_a}{(k_1 + k_2) [\text{IsoB}] + k_{13} [\text{CO}]} = R_{\text{Neop}} \quad (\text{Eq. 4})$$

As mentioned above, the reaction of $^1\text{CH}_2$ with ketene is negligible at the ratio of isobutane to ketene used and is omitted.

If we assume that the rate of reaction of $^1\text{CH}_2$ with either isobutane or CO does not change very much with a change in wavelength, then the yield of both neopentane and isopentane will be proportional to the quantum yield of $^1\text{CH}_2$ produced by photolysis

at each wavelength. The variations of pentane yields with the pressure of CO are shown in figures 3-3, 3-4, and 3-5.

The Ketene-Isobutane-Xenon Photolysis System

Photolyses of 55.5 Torr of the standard photolysis mixture (100 isobutane: 10 ketene: 1 propane) to which more than 100 Torr of xenon had been added were done at 313 nm and 277 nm. The yields of the products and the exact conditions are summarized in Tables 3-I and 3-III. At each wavelength, the ratio of neopentane to isopentane with xenon present was larger than without xenon, but the total quantum yield was the same. In one extra experiment done at 277 nm, 2.3 Torr of oxygen was added to the xenon mixture, and the ${}^3\text{CH}_2\text{-O}_2$ measured for these conditions was 60%. The fraction of ${}^3\text{CH}_2$ present thus increases upon the addition of so-called inert gases as evidenced by the increase in both the neopentane to isopentane ratio and the ${}^3\text{CH}_2\text{-O}_2$. This is in agreement with the findings of other workers.¹⁵⁻²⁰

A similar experiment with xenon and oxygen to compare the total quantum yield in the presence of O_2 with the total quantum yield in the absence of O_2 and so determine the percent of ${}^3\text{CH}_2$ was not made at 313 nm. Nevertheless, the percent of ${}^3\text{CH}_2$ formed in the presence of xenon at 313 nm can be estimated. As the data in Table 3-I indicate, 30% of the butyl radicals recombine to

form the pentane products (reactions 10 and 11). The rest of the butyl radicals, 70%, disproportionate and recombine (reactions 6, 7 and 9) to form isobutane and isobutene and the two octanes. The isobutene and the octanes were measured in this xenon experiment at 313 nm and since their yields are 70% of the total yield of butyl radicals, the yield of butyl radicals can be calculated. Since only $^3\text{CH}_2$ forms the butyl radicals, the percentage of these divided by the total quantum yield is the percentage of methylene that is $^3\text{CH}_2$. This calculation is equivalent to the method used to determine the percent of $^3\text{CH}_2$ with the oxygen experiments, $^3\text{CH}_2\text{-O}_2$. When evaluated as just described, the percent of $^3\text{CH}_2$ present in the photolysis of the standard mixture and 115 Torr of Xe at 313 nm was found to be 51%. The observed ratio of neopentane to isopentane for this experiment and for the Xe experiment at 277 nm and of each $^3\text{CH}_2\text{-O}_2$ have been included in figure 3-2. These data fall right in line with those of experiments in which an "inert" gas was not added.

Discussion of the Isobutane Results

General Introductory Summary

There have been several measurements of the fraction of $^3\text{CH}_2$ formed in ketene and diazomethane photolyses. The fractions measured do not always agree and depend on precursor, photolyzing wavelength, added gases, and the method used to determine the amount of $^3\text{CH}_2$ present. In this chapter we discuss the variations of the percent of $^3\text{CH}_2$ as a function of wavelength in terms of two mechanisms for the formation of $^3\text{CH}_2$. We believe that in order to explain the results presented in the previous chapter there must be two sources of $^3\text{CH}_2$, one being an intersystem crossing from the $^1\text{CH}_2$ to the $^3\text{CH}_2$ (a spin forbidden process), the other a direct absorption of the photolyzing light to form the $^3\Lambda_2$ excited state of ketene (a spin and symmetry forbidden process) and the subsequent decomposition of the $^3\Lambda_2$ state to $^3\text{CH}_2$ and CO. The transition from the ground state ($^1\Lambda_1$) of ketene to the $^3\Lambda_2$ state predominates at longer wavelengths (longer than 320 nm). The intersystem crossing from $^1\text{CH}_2$ to $^3\text{CH}_2$ is a bimolecular process with the colliding molecule providing a coupling between the singlet and triplet states of methylene and thereby easing the restrictions on spin. This is the major source of $^3\text{CH}_2$ at shorter wavelengths. The results of the CO experiments

provide a method of determining the amounts of $^1\text{CH}_2$ and $^3\text{CH}_2$ produced directly from the photodecomposition of ketene. This can be used together with the data for the intersystem crossing at shorter wavelengths to determine the amount of $^3\text{CH}_2$ formed under different conditions.

The mechanism of the intersystem crossing and its application to the less complicated system at the shorter wavelengths (277 nm) will be discussed first. The evidence for and the description of the mechanism involving triplet ketene will be discussed next, and then the two mechanisms will be combined to describe the photolysis system at intermediate wavelengths. The last section will describe the differences between the 214 nm photolysis system and the photolysis systems at the other wavelengths and will discuss the evidence for a third electronic state of methylene, the $^1\text{B}_1$ state, produced at 214 nm.

I A Review of Three Possible Mechanisms for the Formation of $^3\text{CH}_2$

In the twelve years since Herzberg^{1,2} first identified the presence of $^3\text{CH}_2$ after the photolysis of diazomethane, several mechanisms for the production of $^3\text{CH}_2$ during the photolysis of ketene or diazomethane have been proposed.³ This discussion will be limited to the details of photolysis of ketene.

In the simplest mechanism, the ketene is assumed to be excited by light to either a triplet state (a spin forbidden transition) or a singlet state which then decomposes, with spin conservation, to $^3\text{CH}_2$ or $^1\text{CH}_2$. (The decomposition of a singlet ketene state to $^3\text{CH}_2$ and $\text{CO}(^3\pi)$, the first excited state of CO, requires far too much energy to be feasible at the wavelengths studied.) However, this mechanism alone cannot explain the apparent increase in the percent of $^3\text{CH}_2$ that occurs when the ketene is photolyzed in the presence of increasing concentrations of

supposedly inert gases. At some point, either the methylene or ketene must be involved in a spin forbidden process. Methylene and ketene are both too simple molecules to be expected to undergo an intramolecular (or spontaneous), spin forbidden intersystem crossing.⁴ Collisions of the excited ketene or the $^1\text{CH}_2$ with other molecules and subsequent intersystem crossing have been suggested to explain the increase in the fraction of $^3\text{CH}_2$ with an increase in the pressure of the added gases.^{1,2,5-9}

Two of the various mechanisms which can explain a bimolecular intersystem crossing are shown schematically in figure 4-1. Scheme A is a bimolecular intersystem crossing of ketene in the first excited singlet state, $^1\text{CH}_2\text{CO}^*$ or actually $^1\text{A}_2$, to the lowest triplet state of ketene, $^3\text{CH}_2\text{CO}^*$ or $^3\text{A}_2$. According to this mechanism, the decomposition of the excited singlet ketene is slow enough to compete with a bimolecular intersystem crossing to the lowest triplet state of ketene. The $^3\text{A}_2$ state then decomposes

to $^3\text{CH}_2$ and CO. Scheme A requires that the percent of $^3\text{CH}_2$ increases as the total pressure of the system increases. Scheme B differs in that the excited singlet state of ketene, $^1\text{CH}_2\text{CO}^*$, decomposes very quickly to $^1\text{CH}_2$ and CO and the bimolecular intersystem crossing is a reaction of the $^1\text{CH}_2$ and not of the $^1\text{CH}_2\text{CO}^*$ or $^1\text{A}_2$ state. At first glance, scheme B also seems to predict that the fraction of $^3\text{CH}_2$ should increase as the total pressure of the system increases. However, once the $^1\text{CH}_2$ is formed, there will be a competition between the intersystem crossing reaction and any other reactions of $^1\text{CH}_2$. This competition will limit the percent of $^3\text{CH}_2$ formed from $^1\text{CH}_2$, so that increasing the total pressure of the system will not increase the percent of $^3\text{CH}_2$.

Scheme A has been discounted by the experimental results of numerous workers^{5, 10-13} who have studied mixtures of ketene and a reactive gas (e.g., propane, n-butane, and methylethyl-ether) and have found a constant ratio of the products of $^3\text{CH}_2$ reaction compared to the products of $^1\text{CH}_2$ reactions. In our work, doubling the pressure of the standard ketene-isobutane mixture

Two possible mechanisms for the production of ${}^3\text{CH}_2$ via a bimolecular intersystem crossing.

did not change either the neopentane to isopentane ratio or the measured percent of $^3\text{CH}_2$, which again discounts scheme A. Only scheme B is left as a description of the production of $^3\text{CH}_2$.

According to scheme B, the photolysis of ketene in the presence of an inert gas, such as xenon, will not affect the total amount of methylene produced, but will increase the percent of $^3\text{CH}_2$ formed in the system. In our work, the presence of Xe during the photolysis of the ketene-isobutane mixture at 313 nm and 277 nm increased the neopentane to isopentane ratio and the measured percent of $^3\text{CH}_2$ ($^3\text{CH}_2\text{-O}_2$), but did not change the total quantum yield. (See Tables 3-I and 3-III.) Voisey⁵, however, found that adding an inert gas to his ketene-ether system decreased the total quantum yield. As will be explained later, this decrease is probably due to the interfering reaction of $^3\text{CH}_2$ with ketene. (See page 114.) Scheme B, a vague and undetailed outline, can explain some of the most prominent features of ketene photolysis, but part of the description is still missing.

II The Mechanism of Intersystem Crossing in Methylene

The details of the mechanism of the intersystem crossing of methylene from the $^1\text{A}_1$ state to the $^3\text{B}_1$ state have not been specified in scheme B. The collision partner, M, induces the

intersystem crossing, but the way in which it affects the $^1\text{CH}_2$ has not been explained.

When the $^1\text{CH}_2$ is produced from the decomposition of the $^1\Lambda_2$ state of ketene, it is formed with some excess energy, if the photolyzing light has more energy than is needed to form $^1\text{CH}_2$ and CO from ketene. The heat of reaction for the decomposition of ketene is 76.4 kcal/mole (see Table 5-VIII) which is smaller than the energy of the photolyzing light at any wavelength used in this study. The excess energy from the photolysis may appear as vibrational energy in the $^1\text{CH}_2$, and this is the assumption made in assigning the relative positions of the methylene and ketene energy levels in figure 4-2b. There are two possible ways for methylene in the $^1\Lambda_1$ state to cross over into the $^3\text{B}_1$ state, and both require a collision at some instant to effect the transition.

A The Intramolecular or Spontaneous Mechanism

In the first conception, a collision of the vibrationally excited $\text{CH}_2(^1\Lambda_1)$ state causes the $\text{CH}_2(^1\Lambda_1)$ to lose some of its vibrational energy to the surrounding molecules. The $\text{CH}_2(^1\Lambda_1)$ in its lowest vibrational level spontaneously or intramolecularly crosses over to the $^3\text{B}_1$ state. This corresponds to pathways a and b of figure 4-2b, a pressure dependent vibrational relaxation of $\text{CH}_2(^1\Lambda_1)$ followed by a fast pressure independent inter-

Figure 4-2a

This diagram is taken in part from references 12 and 19.

T_0 is between 40 and 50 kcal/mole. The difference between the 1A_2 and 3A_2 states is 30-40 kcal/mole.

Figure 4-2a

Figure 4-2b

A qualitative Jablonski diagram showing the different states of ketene and methylene.

The energies of the states of ketene are taken from Laufer and Keller,²¹ and the position of the second excited singlet state, 1A_1 , is estimated from the absorption spectrum of ketene and corresponds to the change in extinction coefficients at 250 nm. The 1A_1 and 3B_1 states of methylene are estimated to be about 1.5 kcal/mole apart.^{1,2,8,12,13} The position of the 1B_1 state of methylene is estimated by Herzberg^{1,2} to be 20-30 kcal/mole above the 1A_1 state of methylene.

The upward arrows 1, 2, 3, and 4 represent the absorption of 366 nm, 313 nm, 277 nm, and 214 nm light by ketene. The downward arrows represent different amounts of vibrational relaxation. The horizontal arrows 5 and 6 represent the decomposition of ketene to CH_2 and CO. The horizontal arrow 7 represents an intersystem crossing from the 1A_2 state to the 3A_2 state in ketene.

Pathways a and b describe vibrational relaxation of $CH_2(^1A_1)$ followed by a crossing from the 1A_1 state with very little vibrational energy to the 3B_1 state. (See references 14 and 15) Pathways d and e describe a crossing from vibrationally excited $CH_2(^1A_1)$ to $CH_2(^3B_1)$ which subsequently undergoes vibrational relaxation. (See references 5, 6, and 8 and also the theoretical calculations of Chang, T. and Basch, H., Chem. Phys. Letters 5, 147 (1970).)

Figure 4-2b

system crossing to the $\text{CH}_2(^3\text{B}_1)$.

According to both Bader and Generosa¹⁴ and Matsen and Klein¹⁵, the rate of the intramolecular intersystem crossing of methylene in the $^1\text{A}_1$ state will be larger at lower vibrational levels. Bader and Generosa use Zener's formula which relates the rate of crossing to the reciprocal of the difference in steepness of the two potential surfaces (here, $\text{CH}_2(^1\text{A}_1)$ and $\text{CH}_2(^3\text{B}_1)$) at their point of intersection and to the reciprocal of the velocity of the nuclei as the molecule approaches the point of intersection. (The velocity of the nuclei will be smallest in the lowest vibrational energies.) Matsen and Klein use Coulson and Zalewski's formula, a more complicated form of Zener's equation, and emphasize that the rate of crossing is proportional to the overlap of the vibrational wavefunctions of the two electronic states. This is a maximum when the nuclear motion is smallest at the point of intersection. In both cases, an acceleration in the vibrational relaxation of the $^1\text{A}_1$ state of methylene will mean an increase in the rate of intersystem crossing. Therefore, those systems having the inert gas with the highest efficiency of vibrational energy transfer should have the largest fraction of $^3\text{CH}_2$.

15. Matsen, F. A. and Klein, D. J., Adv. Photochem. 7, 1 (1969).

B The Bimolecular (Intermolecular) Mechanism

The second possible mechanism by which methylene may cross over from the 1A_1 state to the 3B_1 state requires an external event, a collision, to effect the crossover. This is opposed to the spontaneous crossover described above. A collision-induced intersystem crossing is typical of molecules in the "resonant limit" of radiationless transition theory.¹⁶ A molecule is said to be in the "resonant limit" when the vibronic energy levels in the molecule are not closely spaced and when the vibronic interaction between the two states is very small.

Anderson, et al.¹⁷ estimated the energy level spacings for the glyoxal intersystem crossing, $^1A_u \rightarrow ^3A_u$ (first excited singlet to lowest triplet) to be large enough to put glyoxal in the resonant limit. Since the energy level spacings are roughly inversely proportional to the size of the molecule, and since ketene and methylene are both smaller than glyoxal, it is expected that they, too, will be in the resonant limit.

In a collision-induced intersystem crossing, the function of a collision partner is to provide a coupling between the two

16. Jortner, J., Rice, S. A., and Hochstrasser, R. M., Adv. Photochem. 7, 149 (1969).

17. Anderson, L. G., Parmenter, C. S., Poland, H. M., and Rau, J. D., Chem. Phys. Letters 8, 232 (1971).

states. The coupling is in the form of a perturbation which broadens the vibronic energy levels of an electronic state so that a "quasi-continuum" of levels results during the time of the collision and a crossing can be made from one electronic state to another. This mechanism is depicted by pathways d and e in figure 5-2b, a collision-induced intersystem crossing and then a vibrational relaxation within the 3B_1 state of methylene. At a given energy level, the larger the coupling provided by the colliding molecule, the faster the rate of intersystem crossing.

C The Evidence Against the Intramolecular Intersystem Crossing

Bader and Generosa,¹⁴ Eder and Carr,⁸ and Cox and Preston⁶ studied the $^1CH_2(^1A_1)$ reactions with trans-butene-2, propane, and ketene, respectively, in the presence of large amounts of relatively unreactive gases. Both Eder and Carr and Cox and Preston found the relative efficiencies in converting 1CH_2 to $^3CH_2(^3B_1)$, i.e., the relative rate of intersystem crossing of 1CH_2 to 3CH_2 , to decrease in the order $Xe > CF_4 \sim N_2 > Ar > He$. Bader and Generosa found the efficiency of CF_4 to be greater than that of Xe, but otherwise agreed with the order of efficiencies found by Eder and Carr. Among the monatomic gases, the efficiency of vibrational transfer from CH_2 should be greatest for He because its translational velocity should be closest to

the velocity of H during a CH vibration. Thus, the order expected if the transfer of vibrational energy were the rate limiting step would be He > Ar > Xe, the opposite of what is found. Therefore, the vibrational relaxation of $^1\text{CH}_2$ must not be the limiting step and the spontaneous molecular intersystem crossing of $^1\text{CH}_2$ to $^3\text{CH}_2$ can not be the correct mechanism.

On theoretical grounds, an intramolecular or spontaneous intersystem crossing is very unlikely. As mentioned before in explaining the bimolecular mechanism, if the density of energy levels for an intersystem crossing of the first excited singlet (1A_u) state of glyoxal ($\text{HC}(\text{CO})\text{C}(\text{CO})\text{H}$) to the lowest triplet (3A_u) state of glyoxal is so small that when there are no collisions this crossing is not observed, it is extremely improbable that such an intersystem crossing would occur in methylene.¹⁷ If the vibronic coupling between the 1A_1 and 3B_1 states of methylene were very large, i.e., if the Franck-Condon factors were very large, methylene could be intermediate between the "statistical limit" (where an intramolecular crossover is possible) and the "resonant limit". However, there is no a priori reason to expect an unusually large vibrational overlap between the 1A_1 and 3B_1 states.

D The Effect of the Nature of the Collision Partner in the
Bimolecular Intersystem Crossing of Methylene

As demonstrated above, the order of the effects of addenda on the rate of intersystem crossing cannot be correlated with the efficiency of vibrational transfer. This leaves the question of what does correlate with the efficiency of an added gas to induce an intersystem crossing in methylene. Since this is a spin-forbidden process, a likely property to test a correlation with is the spin-orbit parameter of the colliding molecule or atom. Since the spin is not a good quantum number for systems in which there is a strong interaction between the orbital angular momentum and the spin, the larger the spin-orbit parameter, the less stringent the restrictions on spin.

The quenching of iodine by several gases was studied by Selwyn and Steinfeld.¹⁸ The quenching process in I_2 is reported to be a collision-induced predissociation from a bound state of I_2 . Selwyn and Steinfeld also apply their theory to the quenching of fluorescence in SO_2 , a collision-induced internal conversion. They found a good correlation of the square of the quenching cross-section with $\mu^{\frac{1}{2}} I\alpha/R_c^3$, where $\mu^{\frac{1}{2}}$ is the reduced mass of the

18. Selwyn, J. E. and Steinfeld, J. I., Chem. Phys. Letters 4, 217 (1969).

collision complex and is proportional to the duration of the collision, I is the ionization energy of the collision partner, R_c is the hard-sphere collision radius, and α is the polarizability of the collision partner. The product $\alpha\mu^{\frac{1}{2}}$ also correlated with the square of the cross-section but not as well as $\mu^{\frac{1}{2}} I\alpha/R_c^3$.

In light of Selwyn and Steinfeld's work, Eder and Carr⁸ tried to correlate the rate of the intersystem crossing of methylene with α , I , $\mu^{\frac{1}{2}}$, $\alpha I\mu^{\frac{1}{2}}/R_c^3$, and the mass of the collision partner and found the best correlation to be with α , the polarizability of the collision partner. A plot of the ratio of the rate of intersystem crossing and the rate of $^1\text{CH}_2$ reaction with propane against polarizability was linear. Eder and Carr also tried a correlation with the spin-orbit parameter of the collision partner, but this failed. The polarizability of each of the gases used in this study and to be discussed later is listed in Table 4-I. These will be of use in explaining the variations in the percent of $^3\text{CH}_2$ formed during the photolysis of ketene.

E The Effect of an Unreactive Gas in a Methylene System

Assuming that the polarizability of the colliding molecule is the major factor in determining the rate of intersystem crossing, then according to the preceding arguments, the percent of $^3\text{CH}_2$ formed will be larger when the colliding molecule has a

larger polarizability. If the colliding molecule does not react with the $^1\text{CH}_2$ chemically, the limiting value of the percent of $^3\text{CH}_2$ is 100% (as per scheme B), but the rate at which the percent of $^3\text{CH}_2$ approaches the limit will depend on the polarizability of the molecule. In other words, although the addition of large amounts of Xe or Ar to the methylene system, in each case, means 100% of the $^1\text{CH}_2$ is converted to $^3\text{CH}_2$, since the polarizability of Ar is less than that of Xe, the pressure of Xe at which all of the $^1\text{CH}_2$ has crossed over to the $^3\text{CH}_2$ is less than the required pressure of Ar.

F The Effect of a Reactive Gas in a Methylene System

If the gas in the methylene system reacts with $^1\text{CH}_2$ to form products (e.g., isobutane reacting with $^1\text{CH}_2$ to form pentanes) and if the gas also induces an intersystem crossing, a competition for the $^1\text{CH}_2$ is set up by the two different events.

The percent of $^1\text{CH}_2$ that is converted to $^3\text{CH}_2$ is given by

$$\frac{[^3\text{CH}_2]}{[^3\text{CH}_2] + [\text{Products}]} = \frac{k_{\text{isc}}}{k_{\text{isc}} + k_{\text{sprod}}} \quad (\text{Eq. 5})$$

where it has been assumed that only $^1\text{CH}_2$ was originally present.

TABLE 4-I

The Polarizabilities of Different Gases Used in Methylene Systems

Gas	Polarizability $\times 10^{-25} \text{ cm}^3$	
Ar	16.6	b
Xe	41.1	b

CO	19.5	b
O ₂	16.0	a

- a Landolt-Bornstein, Zahlenwerte und Funktionen, Vol.I, part 3, page 510, Springer-Verlag, Berlin.(1951).
- b Bridge, N. J. and Buckingham, A. D., J. Chem. Phys. 40, 2733 (1964); Proc. Roy. Soc. A295, 334 (1966).
- c Hanney, H. B. and Smyth, C. P., J. Am. Chem. Soc. 68, 1357 (1946).

Equation 5 indicates that the percent of $^3\text{CH}_2$ formed is independent of the pressure of the reactive gas (as long as the concentration of the reactive gas is large enough so that it is the major reactant). This agrees with our experiments at 313 nm in which the pressure of isobutane was doubled but neither the measured percent of $^3\text{CH}_2$ ($^3\text{CH}_2\%-\text{O}_2$) nor the neopentane to isopentane ratio changed.

As above, the polarizability of M is assumed to be the major factor determining the magnitude of k_{isc} . If k_{sprod} is the same for two different molecules, the percent of $^3\text{CH}_2$ will be determined by the polarizability alone. As long as there is a significant reaction of $^1\text{CH}_2$ with M, i.e., as long as k_{sprod} is not negligible, the amount of $^3\text{CH}_2$ formed from $^1\text{CH}_2$ is always limited by k_{sprod} .

Clearly, if this mechanism is operative, the reaction represented by k_{isc} must be added to the reaction scheme presented in the chapter of results, Chapter 3.

G The Percent of $^3\text{CH}_2$ Formed from $^1\text{CH}_2$ During the Photolysis of Ketene-Alkane Mixtures at Short Wavelengths

The polarizabilities of the alkanes (see Table 4-I) are at least as large as that of Xe and, therefore, must also induce the intersystem crossing of $^1\text{CH}_2$. The percent of $^3\text{CH}_2$ measured by

adding O_2 ($^3CH_2\text{-}O_2$) as described in Chapter 3, is the percent or fraction of methylene formed during the photolysis of the ketene-isobutane mixture which is 3CH_2 , but it is not necessarily the amount of 3CH_2 formed directly from the photodecomposition of ketene. The fraction of 3CH_2 is a measure of the sum of the amount of 3CH_2 formed directly from the photolyzed ketene, ϕ_t , and the amount of 3CH_2 formed by the intersystem crossing of 1CH_2 . This can be expressed as follows,

$$f(^3CH_2) = \phi_t + \frac{\phi_s (k_3 [IsoB] + k_{isc} [M])}{(k_1 + k_2 + k_3) [IsoB] + k_{isc} [M]} \quad (\text{Eq. 6})$$

where k_3 refers to the collision-induced intersystem crossing by isobutane:

In the absence of any added gases in the ketene-isobutane mixtures, i.e., $[M] = 0$, the fraction of 3CH_2 formed during the photolysis is

$$f(^3CH_2) = \phi_t + \frac{\phi_s k_3}{k_1 + k_2 + k_3} \quad (\text{Eq. 7})$$

In the presence of large amounts of unreactive gas, M, Eq. 6 predicts that $f(^3CH_2)$ will approach 1.0 as expected. Since the fraction of 3CH_2 formed during the photolysis is known for some conditions, if ϕ_t , ϕ_s , or $k_3/(k_1 + k_2 + k_3)$ were known, the $f(^3CH_2)$ could be calculated for any conditions.

At wavelengths shorter than 290 nm, but longer than 250 nm, the quantum yield of CO for ketene photolysis is independent of pressure.^{6,9,11,19} This suggests that any excited ketene present has a very short lifetime with respect to its decomposition to methylene and carbon monoxide. The absorption of light in the 250 nm- 380 nm wavelength region has been attributed to the 1A_2 state \leftarrow 1A_1 (ground) state transition in ketene.^{20,21} (An unambiguous absorption to the 3A_2 state has not been identified, even at long wavelengths.) 1A_2 , the lowest excited singlet state of ketene, must be the state reached by the absorption of 290 nm and responsible for the decomposition of ketene. Since 1A_2 is the state of ketene which is decomposing, the products must be 1CH_2 and $CO(^1\Sigma)$. Thus, all of the methylene produced in this wavelength region must be $^1CH_2(^1A_1)$ and so $\phi_s = 1.0$.

In this wavelength region, the fraction of 3CH_2 is due only to the intersystem crossing reaction, i.e., $\phi_t = 0$, and as long as the alkane is the major reactant, equation 7 becomes

$$f(^3CH_2) = \frac{k_3}{k_1 + k_2 + k_3}$$

When the ketene-isobutane mixture was photolyzed at 277 nm, the

-

20. Dixon, R. N. and Kirby, G. H., Trans. Faraday Soc. 62, 1406 (1966).
21. Laufer, A. H. and Keller, R. A., J. Am. Chem. Soc. 93, 61 (1971).

measured percent of $^3\text{CH}_2$ was 36% and therefore, $k_3/(k_1+k_2+k_3)=0.36$ and $k_3/(k_1+k_2)=0.56$. Thus, as long as isobutane is the major reactant, a ketene-isobutane reaction mixture always contains at least $36 \pm 4\%$ of $^3\text{CH}_2$.

Bell⁹ photolyzed mixtures of diazomethane and propane in the presence of several gases including argon, xenon, and nitrogen. He measured the ratio $k_{isc}/(k_1+k_2)$ for each gas. If these three ratios for argon, xenon, and nitrogen are plotted against the polarizability of the added gas and if the ratios from our work with isobutane and Ho and Noyes's¹¹ work with propane are added, the result is a straight line as shown in figure 4-3. Since Hase and Simons²² found the rate of reaction of $^1\text{CH}_2$ with isobutane to be the same as with propane, i.e., (k_1+k_2) is the same for propane and isobutane, we can use Ho and Noyes's data to check the consistency of our method of evaluating $k_3/(k_1+k_2)$. Ho and Noyes photolyzed mixtures of ketene and propane at 270 nm, so that for propane, $k_3/(k_1+k_2+k_3)$ is 0.27 and $k_3/(k_1+k_2)$ is 0.37. The value of $k_3/(k_1+k_2)$ agrees well with the values in figure 4-3. (Note that $k_3=k_{isc}(M)$.)

As Bell mentions, these ratios do not agree with Eder and Carr.⁸ One of the experimental reasons for this discrepancy may be found

22. Hase, W. L. and Simons, J. W., J. Chem. Phys. 54, 1277 (1971).

Figure 4-3

in the variation of the ratio of propane to ketene in Carr's work. Carr kept the total pressure of the reactants constant and the amount of ketene constant and varied the ratio of inert gas to propane. Bell points out that the polarizability of propane is larger than the polarizability of any of the gases Carr added. This means that Carr replaced a molecule effective in inducing an intersystem crossing of $^1\text{CH}_2$ with a molecule that is less effective. Carr's method has the disadvantage of decreasing the ratio of propane to ketene when the inert gas is added.

Although the larger concentration of inert gas means that more $^1\text{CH}_2$ crosses over to $^3\text{CH}_2$ (which is removed by the O_2 which is present), it also means that the ketene begins to compete with propane for the $^1\text{CH}_2$ which further complicates the system. As Bell emphasizes, however, the exact reasons for the differences between the ratios of $k_{\text{isc}}(\text{M})/(k_1+k_2)$ are not known.

III The Reaction of Ketene with $^1\text{CH}_2$ and $^3\text{CH}_2$

In the preceding section, we have assumed that the reactions of both methylenes with ketene were negligible compared to the reactions with isobutane. If the reactions with ketene were not negligible, our measurements of the percent of $^3\text{CH}_2$ would be in error. The determination of the percent of $^3\text{CH}_2$ is based on measurements of the total quantum yield, which is defined in Chapter 3, page 76, as the sum of the yields of the products of

the reactions of both methylenes with isobutane. The total quantum yield does not include reactions of both methylenes with ketene and as long as these are negligible, the total quantum yield is a perfectly valid measure of the amount of methylene produced.

A $^1\text{CH}_2$ and Ketene

Eder and Carr⁸ found the rate of reaction of $^1\text{CH}_2$ with ketene was one fourth the rate of reaction of $^1\text{CH}_2$ with propane at 313 nm. Since the ratio of propane to ketene is 10 to 1, only 2.5% of the $^1\text{CH}_2$ is expected to react with ketene and this would be well within our experimental error. Indeed, when the concentration of isobutane was doubled and the ketene-isobutane mixture was photolyzed at 313 nm in the presence of O_2 , the total quantum yield was no different from the total quantum yield measured when the standard mixture was photolyzed with O_2 at 313 nm. Thus, our measurements confirm that the ratio of the rate of the $^1\text{CH}_2$ reaction with ketene compared to the rate of the $^1\text{CH}_2$ reaction with isobutane is not much larger than 0.25. Dees and Setser¹² estimate that this ratio in the ketene-n-butane system is 0.5. Thus, in our system, where the ratio of isobutane to ketene is 10:1, and if isobutane and n-butane have the same relative reactivity with respect to $^1\text{CH}_2$, 5% of the $^1\text{CH}_2$ will react with ketene which is again within our experimental error. Considering these findings, it is safe to conclude that at concentrations of isobutane to ketene of at least 10:1, the reaction of $^1\text{CH}_2$ with ketene is

negligible compared to the reaction with isobutane.

B $^3\text{CH}_2$ and Ketene

When the amount of isobutane in the standard mixture was doubled, the total quantum yield at 313 nm was the same as found when the standard mixture was photolyzed (see Table 3-III). Since the reaction of $^1\text{CH}_2$ with ketene is negligible, the unchanged total quantum yield in the absence of O_2 must mean that the reaction of $^3\text{CH}_2$ with ketene is also negligible in mixtures having a ratio of at least 10:1. If the $^3\text{CH}_2$ reacted to a significant extent with ketene, doubling the isobutane concentration would increase the total quantum yield, as it was defined above.

In their study of the photolysis of the ketene-n-butane system at 320 nm, Dees and Setser¹² estimate the reaction of $^3\text{CH}_2$ with ketene to be twenty times faster than the reaction with n-butane. If this were also true in the isobutane system where the ratio of isobutane to ketene is 10:1, two thirds of the $^3\text{CH}_2$ would react with ketene and one third with isobutane. Then, doubling the isobutane concentration would mean that half of the $^3\text{CH}_2$ would react with the isobutane and so the total quantum yield, the measured $^3\text{CH}_2\%-\text{O}_2$, and the neopentane to isopentane ratio would increase. This did not occur.

Most workers have found hydrogen abstraction by $^3\text{CH}_2$ to be about ten times faster from a secondary C-H bond than from a primary C-H bond.²³ Thus, if a relative reactivity of 1.0 is assigned to a primary C-H bond, the "total relative reactivity" of n-butane is $6 + 4(10) = 46$ and of propane is $6 + 2(10) = 26$.

This work shows that the tertiary H is abstracted from isobutane about 60 times faster than the primary H of the C-H bond (see Table 3-III). Hence, the "total relative reactivity" of isobutane is 69. Simplistically assuming that no other factor is important in determining the ratio of reactivities, the isobutane is 1.4 times as reactive as n-butane towards $^3\text{CH}_2$. However, this is not enough to account for the difference between Setser's results and our findings with isobutane.

Dees and Setser's estimate of the proportion of $^3\text{CH}_2$ reacting with ketene compared to that with n-butane was based on the ratio of the products of methyl radicals to the products of the butyl radicals. However, they did not measure the disproportionation product of the sec-butyl radical. They concluded that the olefin forming reaction was negligible and cited Ring and Rabinovitch⁷ who used 0.64 for the ratio of disproportionation to recombination rates for the sec-butyl radical. Kraus and Calvert²⁴, whom

24. Kraus, J. W. and Calvert, J. G., J. Am. Chem. Soc. 79, 5921 (1957).

whom Setser did not cite, found this ratio to be 2.27. Since Dees and Setser¹¹² do not show the observed yields of octanes, a correction for the disproportionation product cannot be made.

Bell⁹ used the results of Ho and Noyes¹¹ to find that the ratio of the rates of reaction of $^3\text{CH}_2$ with ketene compared to that with propane is 6 ± 2 . Again being simplistic, the "total relative reactivity" of isobutane towards $^3\text{CH}_2$ is 2.7 times that of propane. Hence, the rate of reaction of $^3\text{CH}_2$ with ketene is 2.3 times as fast as that with isobutane. In this case, less than 20% of the $^3\text{CH}_2$ reacts with ketene. When $^3\text{CH}_2$ is 50% of both methylenes, less than 10% of the total amount of methylene will be reacting with ketene via reaction 14. This is within the error limits of our experiments, if Bell's estimate is correct.

As mentioned earlier, Voisey⁵ found a decrease in his ether reaction yield when the ketene-ether mixture was photolyzed in the presence of an inert gas. If the $^3\text{CH}_2$ reacts much faster with ketene than with the ethyl-methyl ether, then, even at a ratio of ten parts of ethyl-methyl ether to one part ketene, the $^3\text{CH}_2$ could be reacting with ketene to a significant extent. As the pressure of the inert gas increased, the amount of $^3\text{CH}_2$ would increase and the yield of ether products would decrease because less methylene would be reacting with ethyl-methyl ether.

IV The Second Source of $^3\text{CH}_2$

A Introduction and Evidence

If the only source of $\text{CH}_2(^3\text{B}_1)$ were the intersystem crossing of $\text{CH}_2(^1\text{A}_1)$, we would not expect a large change in the percent of $^3\text{CH}_2$ with a change in the photolyzing wavelength. However, there is ample evidence in many ketene photolysis studies for a large and abrupt increase in the percent of $^3\text{CH}_2$ as the photolyzing wavelength increases from 250 nm to 370 nm. This abrupt change in the $^3\text{CH}_2$ products occurs at about 320 nm and has been noted by several workers, but they have not proposed an adequate explanation for it. ^{5,10,11,25}

Figure 3-1 depicts the ratio of neopentane to isopentane and the $^3\text{CH}_2\text{-O}_2$ (the percent of $^3\text{CH}_2$ measured by the oxygen experiments) as a function of the photolyzing wavelength. For comparison, the variation in the ratio of the quantum yield of ethylene to the quantum yield of ethylene in the presence of O_2 when ketene alone was photolyzed is also shown. This graph was taken from DeGraff and Kištiakowsky.¹⁹ This ratio, $\phi_{\text{C}_2\text{H}_4} / \phi_{\text{C}_2\text{H}_4(\text{O}_2)}$, represents the ratio of triplet to singlet products in the photolysis of ketene alone. The graph includes the values of the ratio found by several other workers; the value at 365 nm is from G. B. Porter²⁶

25. Strachan, A. N. and Thornton, D. E., Can. J. Chem. 46, 2353 (1968).

and the value at 270 nm is from Strachan and Noyes.²⁷ All three graphs show a distinct change in the percent of $^3\text{CH}_2$ or $^3\text{CH}_2$ reaction products at 320 nm. Mitschelle's¹⁰ data for the ketene-propane system photolyzed at several wavelengths between 250 nm and 366 nm shows this same abrupt change at 320 nm.

Several workers^{25,27,28,29} have investigated the pressure dependence of ketene decomposition at several wavelengths. Although nothing specific can be said about $^3\text{CH}_2$ in these experiments, there is evidence that more than one process is involved in the photolytic decomposition of ketene. The quantum yield for ketene decomposition at 270 nm is independent of the pressure of ketene or of an added unreactive gas, C_4F_8 or SF_6 . The quantum yield in the 330 nm to 366 nm wavelength region decreases as the pressure of ketene is increased or when an unreactive gas, C_4F_8 or SF_6 , is added to increase the total pressure. In the intermediate wavelength region around 313 nm, the quantum yield is pressure independent up to a certain pressure of ketene (250 Torr, Strachan and Thornton's results²⁵) and beyond that is pressure dependent, although the pressure dependence is much smaller than

26. Porter, G. B., J. Am. Chem. Soc. 79, 1878 (1957).

27. Strachan, A. N. and Noyes, W. A., Jr., *ibid.* 76, 3258 (1954).

28. Taylor, G. B. and Porter, G. B., J. Chem. Phys. 36, 1353 (1962).

29. Porter, G. B. and Connolly, B. T., *ibid.* 33, 81 (1960).

that at the longer wavelengths. Strachan and Thornton found that C_4F_8 and SF_6 added to 50 Torr of ketene decreased the quantum yield and they attributed the increased efficiency in decreasing the quantum yield to an increase in the number of vibrational degrees of freedom compared to ketene.

The pressure dependence in ketene decomposition implies the presence of an excited state of ketene that lives long enough before decomposition to lose energy in collisions. The longer lifetime in the presence of a gas with more vibrational degrees of freedom implies that the excited state of ketene vibrationally relaxes to an energy where further relaxation successfully competes with decomposition to CH_2 and CO .

B The Absorption Spectrum of Ketene

The absorption spectrum of ketene is expected to be typical of that of carbonyl compounds. Aldehydes and ketones have a weak absorption band in the 340 nm to 230 nm region which is attributed to a forbidden $\pi \leftarrow n$ singlet-singlet transition. A second, much stronger absorption band begins at wavelengths shorter than 220 nm which is believed to be related to an allowed $\pi^* \leftarrow \pi$ transition. A third, very weak absorption band ($\epsilon \approx 10^{-3}$ liters/mole-cm) occurs near 400 nm, often close to the

long wavelength limit of the $\pi^* \leftarrow n$ transition. This is attributed to the doubly forbidden (spin and symmetry forbidden) $\pi^* \leftarrow n$ transition, the singlet ground state to first triplet state transition.³⁰

The absorption spectrum of ketene^{20,21,31} in the visible and near ultraviolet consists of two regions, a weak ($\epsilon \approx 10$ liters-mole⁻¹cm⁻¹) absorption with a maximum at 330 nm and a strong absorption ($\epsilon \approx 10^3$ liters-mole⁻¹cm⁻¹) below 240 nm. (See figure 2-3.) The spectrum consists of broad, diffuse vibrational bands in both regions and extends into the visible to a limit at 473.5 nm.²⁰ Dixon and Kirby²⁰ searched the absorption spectrum in the 260 nm to 480 nm region for evidence of the lowest triplet ($^3\Lambda_2$) state of ketene. They thought they had observed a distinct change in the vibrational spacings near 385 nm and attributed the absorption at longer wavelengths to the $^3\Lambda_2 \leftarrow ^1\Lambda_1$ transition. The absorption at wavelengths shorter than 385 nm was attributed to the $^1\Lambda_2 \leftarrow ^1\Lambda_1$ (ground) or $\pi^* \leftarrow n$ transition. However, the data implied an upper limit for the dissociation of ketene of 61 kcal mole⁻¹. This was much lower than the heat of dissociation calculated from the heats of formation of ketene, methylene and carbon monoxide (78 kcal mole⁻¹).

30. Calvert, J. G. and Pitts, J. N., Jr., Photochemistry, John Wiley and Sons, Inc., New York, 1966.

31. Sauer, K. H. and Kistiakowsky, G. B., J. Am. Chem. Soc. **80**, 1066 (1958).

Because of the disagreement between Dixon and Kirby's values and thermochemical data, Laufer and Keller²¹ reinvestigated the absorption spectrum of ketene and concluded that the change in vibrational spacing was not distinct, but was continuous and so probably due to the anharmonicity of the vibration. They did not rule out the possibility of a direct absorption from the singlet ground state to the triplet (3A_2) state, but suggested that it might be hidden under the 1A_1 (ground) to 1A_2 absorption.

This singlet to triplet absorption is doubly forbidden, so its extinction coefficient will be very small. The absorption will be even weaker if the minimum of the potential energy surface of the 3A_2 state is shifted with respect to the 1A_1 state so that the Franck-Condon transitions to the 3A_2 state must occur from the vibrational level of 1A_1 larger than $v=0$. (See figure 4-2.) If this is true, the strength of the singlet to triplet absorption will increase with an increase in temperature. Strachan and Thornton²⁵ and Taylor and Porter²⁸ studied ketene absorption at several temperatures and observed an increase of light absorption by ketene at the wavelengths 313 nm, 334 nm, and 366 nm as the temperature increased. The largest increase in absorption with increasing temperature was at 366 nm where the percent of 3CH_2 is largest. The increase in absorption parallels the increase in the quantum yield of ketene decomposition which also occurs with an increase in temperature.

Although the direct absorption from the 1A_1 (ground) state to the 3A_2 state has not yet been observed, similarities between the absorption spectrum of ketene and of other carboxyls (aldehydes and ketones) suggest that it does occur. The kinetic data discussed in the previous section (and the results of the CO experiments to be discussed in a later section) indicate a process other than the intersystem crossing of methylene from the 1A_1 state must occur at longer wavelengths to explain the increase of methylene in the 3B_1 state, 3CH_2 . The production of the 3A_2 state of ketene by direct absorption of light at wavelengths longer than 320 nm and its subsequent decomposition to $CH_2(^3B_1)$ and $CO(^1\Sigma)$ is the most likely process.

C The Excited States of Ketene

In the two previous sections we have discussed the arguments and evidence (the absorption spectrum of ketene and the abrupt change in the observed percentage of 3CH_2 at 320 nm) which necessitate the postulation of two different processes of formation of 3CH_2 in ketene photolyses. A summary describing how both processes occur and the conditions under which each predominates is now in order.

The absorption spectrum of ketene involves transitions from

the ground, 1A_1 , state to the three excited states, 1A_1 , 1A_2 , and 3A_2 . The relative energies and qualitative potential energy surfaces are shown in figure 4-2. The absorption of 214 nm light results in a transition from the ground state, 1A_1 , to the second excited singlet, 1A_1 . This is an allowed transition (a $\pi^* \leftarrow \pi$ transition) and the oscillator strength is expected to be large; the observed extinction coefficient ($\epsilon \approx 2000$ liters-mole $^{-1}$ cm $^{-1}$) reflects this. Absorption in the region 260 nm to 380 nm and beyond corresponds to transitions to both the 1A_2 and 3A_2 states. The stronger absorption corresponds to a transition from the 1A_1 to the 1A_2 state. This is a symmetry forbidden transition; its oscillator strength and therefore its extinction coefficient are expected to be much smaller ($\epsilon = 10$ liters mole $^{-1}$ cm $^{-1}$) than for the transition from the 1A_1 (ground) state to the 1A_1 state. A transition from the 1A_1 state to the 3A_2 state is symmetry forbidden and also spin forbidden. The vibrational overlap for this transition is larger at the higher vibrational levels of the 1A_1 ground state ($v > 0$). Because of the spin and symmetry forbiddenness and because of the small vibrational overlap between the ground state predominant at room temperature and the 3A_2 excited state, the oscillator strength and extinction coefficient are expected to be very small. This direct absorption to the 3A_2 state must have a maximum at a wavelength longer than 320 nm (although the exact position has not been determined) and

might be hidden beneath the stronger ${}^1A_2 \leftarrow {}^1A_1$ absorption.

The decomposition from the 1A_2 state of ketene can be described with the aid of figure 4-2. Absorption of the shorter wavelengths, e.g., 270 nm, results in a highly vibrationally excited 1A_2 state of ketene. Since at this wavelength, the primary quantum yield for ketene decomposition is pressure independent, the lifetime of the 1A_2 state of ketene must be very short prior to decomposition into $CH_2({}^1A_1)$ and CO. In this region the intersystem crossing from $CH_2({}^1A_1)$ is the only source of $CH_2({}^3B_1)$; ϕ_s (the quantum yield of 1CH_2) is equal to 1.0. As the photolyzing wavelength is increased, the 1A_2 state of ketene is formed with less vibrational energy. At the energies reached by the intermediate wavelengths, such as 313 nm, enough vibrational energy could be lost by one or two strong collisions that the resultant energy would be close to the minimum energy required for decomposition to 1CH_2 and CO. At this lower energy, the decreased rate of decomposition of the 1A_2 state of ketene to 1CH_2 and CO decreases the quantum yield of ketene decomposition. This mechanism is basically the same as that proposed by Strachan and Thornton for the photolysis of ketene at 313 nm. Close to 366 nm, the 1A_2 state of ketene does not have enough energy to decompose to 1CH_2 and CO and thus, the 1A_2 state is expected to have a long lifetime and the quantum yield for ketene

decomposition from the 1A_2 state will be very small and pressure dependent. At this wavelength, the observed percent of 1CH_2 is so small, that not only the quantum yield but also the absorption coefficient for the 1A_2 transition must be extremely small if not zero, and almost all of the absorption must be to the 3A_2 state of ketone.

At wavelengths longer than approximately 320 nm, direct absorption to the 3A_2 state of ketene and the subsequent decomposition of the 3A_2 state to $CH_2(^3B_1)$ and CO becomes the major pathway for ketene decomposition. This means that as the photolyzing wavelength increases beyond about 320 nm, ϕ_t (the quantum yield of 3CH_2 production) becomes larger and ϕ_s becomes smaller. At the same time, $\phi_s + \phi_t$, the total quantum yield of methylene, becomes less than 1.0 because of the reduced decomposition of both excited states. It is important to note that even at 380 nm,¹¹ neither the ratio of isobutane to n-butane nor the butane yield relative to the CO yield in a ketene-propane system changes when the total pressure changes from 60 Torr to 200 Torr. Thus, even at the longest wavelengths that have been studied, the inter-system crossing of 1A_2 ketene to 3A_2 ketene is not important.

The next objective is to find ways to measure the individual quantum yields of 1CH_2 and 3CH_2 produced when ketene is photolyzed.

V Discussion of the CO Experiments and the Measurements of ϕ_s

A The Determination of ϕ_s from the CO Experiments

As mentioned earlier (Chapters 1 and 3) CO reacts with both $^1\text{CH}_2$ and $^3\text{CH}_2$. The reaction of $^3\text{CH}_2$ with CO is faster than its reaction with isobutane so that in the presence of only 60 Torr of CO, there is no measurable reaction of $^3\text{CH}_2$ with isobutane at 50 Torr. CO can also induce the intersystem crossing of $^1\text{CH}_2$ to $^3\text{CH}_2$ via the reaction

In these experiments, it is impossible to distinguish between the reaction $\text{isc}(\text{CO})$ and 13.

Reaction $\text{isc}(\text{CO})$ is included within reaction 13 in the equations for the rates of formation of isopentane and neopentane (Eqs. 3 and 4) which were derived assuming a steady state rate of formation for $^1\text{CH}_2$. Equations 3 and 4 apply when only $^1\text{CH}_2$ is reacting with CO. Reaction 13 and equations 3 and 4 are repeated here for the reader's convenience (see also page 84 of Chapter 3).

$$R_{\text{IsoP}} = \frac{d}{dt} [\text{IsoP}] = \frac{k_1 [\text{IsoB}] \phi_s I_a}{(k_1 + k_2) [\text{IsoB}] + k_{13} [\text{CO}]} \quad (\text{Eq. 3})$$

$$R_{\text{NeoP}} = \frac{d}{dt} [\text{NeoP}] = \frac{k_2 [\text{IsoB}] \phi_s I_a}{(k_1 + k_2) [\text{IsoB}] + k_{13} [\text{CO}]} \quad (\text{Eq. 4})$$

Equations 3 and 4 predict that, at a given pressure of CO larger than 60 Torr, the ratio of the isopentane or neopentane yield³² at one wavelength compared to the yield at a second wavelength is the ratio of the quantum yields of $^1\text{CH}_2$, ϕ_s , at those wavelengths. The pentane yield ratios are calculated from figures 3-3, 3-4, and 3-5 (the plots of the pentane yields versus the pressure of CO added to the standard photolysis mixture). For example,

$$\frac{R_{\text{IsoP}}(\text{at } 313 \text{ nm}) \text{ for } P_{\text{CO}}}{R_{\text{IsoP}}(\text{at } 277 \text{ nm}) \text{ for } P_{\text{CO}}} = \frac{\phi_s (\text{at } 313 \text{ nm})}{\phi_s (\text{at } 277 \text{ nm})}$$

This method assumes that k_1 , k_2 , and k_{13} do not change very much with wavelength. If ϕ_s is known at one wavelength, it can be calculated at each of the other wavelengths. As mentioned above, $\phi_s = 1.0$ at 277 nm. Thus the ϕ_s at each of the other wavelengths are calculated from figures 3-3, 3-4, and 3-5 at both 120 Torr of CO and 200 Torr of CO as follows: $\phi_s(214 \text{ nm}) = 1.0$, $\phi_s(313 \text{ nm}) = 0.75-0.80$, $\phi_s(322 \text{ nm}) = 0.70-0.75$, and $\phi_s(330 \text{ nm}) = 0.19-0.20$.

B The Fraction of $^3\text{CH}_2$ Determined from ϕ_s

Earlier (page 106) the fraction or percent of $^3\text{CH}_2$ was expressed as a sum of the amount of $^3\text{CH}_2$ formed directly from the photolyzed ketene, ϕ_t , and the amount of $^3\text{CH}_2$ formed from the intersystem

32. The pentane yields are the rates of formation multiplied by the photolysis time which was the same in all of the CO experiments.

crossing of $^1\text{CH}_2$, equation 6. For convenience, equation 6 is reproduced below. In deriving equation 6, we have assumed that k_{isc} , k_1 , k_2 , and k_3 (the reactions of $^1\text{CH}_2$ with the diluent gas and with isobutane) do not depend on the photolyzing wavelength and that $\phi_s + \phi_t = \phi_M = 1.0$.

$$f(^3\text{CH}_2) = \phi_t + \frac{\phi_s (k_3[\text{IsoB}] + k_{isc}[\text{M}])}{(k_1 + k_2 + k_3)[\text{IsoB}] + k_{isc}[\text{M}]} \quad (\text{Eq. 6})$$

At 277 nm, the value of the ratio $k_3/(k_1 + k_2 + k_3)$ was determined (page 108) to be 0.35 and can be used with equation 6 to calculate the fractions of $^3\text{CH}_2$ present under different reaction conditions if ϕ_s or ϕ_t is known for each photolyzing wavelength.

As before, when $M = 0$, i.e., when there is no added diluent gas equation 6 becomes equation 7,

$$f(^3\text{CH}_2) = \phi_t + \frac{\phi_s k_3}{k_1 + k_2 + k_3} \quad (\text{Eq. 7})$$

Using 0.35 for the value of $k_3/(k_1 + k_2 + k_3)$ and ϕ_s as calculated from the CO experiments above, the fractions of $^3\text{CH}_2$ are 0.35, 0.48-0.51, 0.51-0.54, and 0.79-0.80 at the wavelengths 214 nm, 313 nm, 322 nm, and 330 nm, respectively. Except for 214 nm, these values are somewhat larger than the percent of $^3\text{CH}_2$ measured via the oxygen experiments. For convenience, Table 4-II, column 1, compares the calculated fraction of $^3\text{CH}_2$ with that measured by the oxygen experiments, $^3\text{CH}_2/\text{O}_2$, for each wavelength.

The use of equation 6 is also applicable for the experiments done when xenon was added to the reaction mixtures which were photolyzed at 277 nm and 313 nm. The presence of xenon in the reaction mixture is expected to increase the fraction of $^3\text{CH}_2$ that is formed the intersystem crossing of $^1\text{CH}_2$. (As discussed before, pages 85, 86, and 114, the presence of xenon did not change the quantum yield of methylene, ϕ_M , in these two experiments.) The ratio of $k_{isc}(\text{Xe})/k_3$ is needed to apply equation 6 to the xenon experiments and is determined from the data of figure 4-3 to be 0.49. Thus, according to equation 6, the fraction of $^3\text{CH}_2$ calculated to be present in the ketene-isobutane-xenon mixtures is 0.65 with 250 Torr of Xe photolyzed at 277 nm and 0.65-0.63 with 115 Torr of Xe photolyzed at 313 nm. The calculated fraction of $^3\text{CH}_2$ in the xenon experiment at 313 nm is larger than the measured $^3\text{CH}_2$ in O_2 .

Thus, the quantum yields of $^1\text{CH}_2$ and $^3\text{CH}_2$ as determined from the CO experiments together with a knowledge of the relative rates of intersystem crossing can be used to determine the percentages or fractions of $^3\text{CH}_2$ and $^1\text{CH}_2$ present in the ketene-isobutane photolysis mixtures. The fraction of $^3\text{CH}_2$ determined in this way however is only in a fair agreement with the percentage of $^3\text{CH}_2$ measured by the oxygen experiments. Possible improvements in the agreement are discussed in the following sections.

TABLE 4-II

Comparison of Calculated and Measured Fractions of $^3\text{CH}_2$

Column 1 lists the fraction of $^3\text{CH}_2$ calculated from Eq. 6. In these calculations $k_3/(k_1+k_2) = 0.54$ for all wavelengths. The value of $k_3/(k_1+k_2)$ was determined from the experiments with and without O_2 at 277 nm as described in the text.

Column 2 lists the fraction of $^3\text{CH}_2$ calculated from Eq. 6, but $k_3/(k_1+k_2)$ was varied with wavelength to give a better agreement with the measured amount of $^3\text{CH}_2$. The ϕ_s used for each wavelength are 0.80 for 313 nm, 0.75 for 322 nm, 0.32 for 330 nm, and 1.0 for 277 nm and 214 nm.

Column 3 lists the percent of $^3\text{CH}_2$ measured from the O_2 experiments and the last two columns list the quantum yield of $^1\text{CH}_2$ measured from the CO experiments and the total quantum yield of both methylenes measured from the total quantum yields.

TABLE 4-II.

Comparison of Calculated and Measured Fractions of $^3\text{CH}_2$

Wavelength	Column 1 (calculated)		Column 2 (calculated)		Column 3 (measured)	ϕ_s/ϕ_M	ϕ_M
	$f(^3\text{CH}_2)$	$k_3/(k_1+k_2)$	$f(^3\text{CH}_2)$	$k_3/(k_1+k_2)$			
214 nm	0.35	0.54	0.45	0.82	49±6	1.0	1.0
277 nm	0.35	0.54	0.35	0.54	36±5	1.0	1.0
313 nm	0.51-0.48	0.54	0.44	0.43	41±5	0.75-0.80	1.0
322 nm	0.54-0.51	0.54	0.48	0.43	42±5	0.70-0.75	1.0
330 nm	0.80-0.79	0.54	0.78	0.43	76±3	0.30-0.32	0.62
277 nm + 250 Torr Xe	0.65	0.54	0.65	0.54	60±6	1.0	1.0
313 nm + 115 Torr Xe	0.65-0.63	0.54	0.58	0.43	52±6	0.75-0.80	1.0

C The Variation of the Quantum Yield of Methylene Production
with Wavelength

In deriving equation 6, we made the assumption that $\phi_s + \phi_t = \phi_M = 1.0$. As already mentioned, the quantum yield for methylene production at the longer wavelengths (330 nm and 366 nm) is less than 1.0. In order to use equation 6 and also 7, we must know the quantum yield for methylene production, ϕ_M , and ϕ_s or ϕ_t . Then for ϕ_s and ϕ_t in equation 6, we substitute ϕ_s/ϕ_M and ϕ_t/ϕ_M . This was done when the fractions of $^3\text{CH}_2$ were calculated for Table 4-II.

Several workers^{6,11,19} have measured the quantum yield of CO production at wavelengths shorter than 290 nm (but longer than 250 nm) in ketene-alkane systems to be 1.0 and in ketene alone to be 2.0 which both imply a ϕ_M of 1.0. At 313 nm and 322 nm, $\phi_M = 1.0$ since the total quantum yields in the isobutane system at both wavelengths are the same as at 277 nm (Table 3-I). At 330 nm, $\phi_M = 0.62$ as calculated from the ratio of the total quantum yields as given in Table 3-I, and ϕ_s as calculated from the CO experiments is 0.19-0.20 and so ϕ_s/ϕ_M is 0.32-0.30, or in other words, 30-32% of all methylene produced from the photolysis of ketene at 330 nm is $^1\text{CH}_2$. At 214 nm, Kistiakowsky and Walter estimated the quantum yield of CO produced during the

photolysis of ketene to be 2 (2.2-2.5) over a range of pressures.³³ Although this was only an estimate, we have assumed that since ϕ_{CO} was approximately 2, and therefore that ϕ_{M} was approximately 1, and was independent of the pressure of ketene, ϕ_{M} in our system should also be 1. In any case, ϕ_{Total} and ϕ_{CO} in our isobutane experiments were set equal to ϕ_{Total} and ϕ_{CO} at 313 nm (where both quantum yields are 1.0) so that ϕ_{S} at 214 nm as calculated from the CO experiments is actually the ratio of $\phi_{\text{S}}/\phi_{\text{M}}$. The results of the CO experiments indicate that, if $\phi_{\text{M}} = 1.0$ at 214 nm, $\phi_{\text{S}} = 1.0$. However, since ϕ_{S} as measured by the CO experiments is actually $\phi_{\text{S}}/\phi_{\text{M}}$, the experimental result is that $\phi_{\text{S}}/\phi_{\text{M}}$ is 1.0 regardless of the value of ϕ_{M} . Thus, the results reveal that all of the methylene produced from the photolysis of ketene at 214 nm is $^1\text{CH}_2$.

VI Changes in the Rate of Intersystem Crossing with the Energy of $^1\text{CH}_2$

The calculated fractions of $^3\text{CH}_2$ at 313 nm and 322 nm were larger than the measured percents of $^3\text{CH}_2$, $^3\text{CH}_2\text{-O}_2$, and although they were both within 20% of the measured values, the agreement should have been better. On the other hand, the calculated

33. Kistiakowsky, G. B. and Walter, T. A., J. Phys. Chem. 72, 3952 (1968).

fraction of $^3\text{CH}_2$ at 214 nm was much smaller than the measured $^3\text{CH}_2\text{^1O}_2$ and these, too, should have agreed better. If the inter-system crossing rate constant, k_3 or $k_{\text{isc}}(M)$, is faster when the methylene has more energy. (when it is formed by photolyses at the shorter wavelengths), the agreement between the calculated fractions of $^3\text{CH}_2$ and $^3\text{CH}_2\text{^1O}_2$, for the photolyses both at 313 nm and 322 nm and at 214 nm would improve. If we change the value of the ratio $k_3/(k_1+k_2)$ at 313 nm (and 322 nm and 330 nm) so that it is smaller than the value at 277 nm, the calculated fractions of $^3\text{CH}_2$ are smaller and agree better with the measured $^3\text{CH}_2\text{^1O}_2$ at those three wavelengths. Thus, our results can be interpreted as indicating a wavelength dependence for $k_3/(k_1+k_2)$, and since k_1 and k_2 probably do not depend on the wavelength used to produce the $^1\text{CH}_2$, the intersystem crossing rate, k_3 , must depend on the wavelength. This is shown in column 2 of Table 4-II. However, both Cox and Preston⁶ and Eder and Carr⁸ claim that according to their results there is no energy dependence in the $k_{\text{isc}}/k_{\text{sprod}}$ ratio. (the ratio of the intersystem crossing rate in singlet methylene compared to the rate of reaction to form products, e.g., k_1+k_2 or k_{16}). As will be discussed later in more detail, it is not very surprising that neither of these workers found a measurable energy dependence of the rate of intersystem crossing; this trend is too small to have been seen in the type of data obtained from their experiments.

A wavelength dependence of k_{isc}/k_{sprod} would not be unexpected. According to the mechanism described above for the intersystem crossing of $\text{CH}_2(^1\text{A}_1)$, the function of the collision partner is to provide a brief coupling of the vibronic energy levels which allow a crossing of methylene from a vibronic energy level of the $^1\text{A}_1$ state to a vibronic level in the $^3\text{B}_1$ state which is almost equal in energy; the small difference in energy is converted to translational and rotational modes in the $^3\text{B}_1$ state. Combinations of the three normal vibrations in methylene result in smaller energy spacings between the higher vibrational states than between the lower vibrational states. Thus, the more vibrational energy $\text{CH}_2(^1\text{A}_1)$ has, the closer together its vibronic energy levels will be, or in other words, the greater the density of states. Because the spacing between vibrational levels within the $\text{CH}_2(^1\text{A}_1)$ manifold of states is smaller at higher vibronic energies, there is a greater chance that the vibronic energy levels of both the $^1\text{A}_1$ and $^3\text{B}_1$ states will be closer than a specified energy difference before a collision. If the energy levels are very nearly equal, the coupling provided by the collision will be more effective, i.e., less of the energy will need to be converted to the translational and rotational modes, and so, the rate of intersystem crossing will be larger.

If the ratio of $k_{isc}(M)/k_{sprod}$ depends on the internal energy of the methylene, an obvious question is: why does there appear to be such a good correlation between the $k_{isc}(M)/k_{sprod}$ ratio determined by our work with isobutane and ketene at 277 nm, and Ho and Noyes's¹¹ work with propane and ketene at 270 nm, and Bell's⁹ work with propane and diazomethane (and various inert gases) at 405 nm and the polarizability of the gases as shown in figure 4-3? The photolysis of ketene at 277 nm results in 25 kcal/mole of energy in excess of the decomposition energy of CH_2CO which must be distributed between the CH_2 and CO as vibrational, rotational, and translational energy. The photolysis of diazomethane at 405 nm results in 48 kcal/mole of energy in excess of the decomposition energy of CH_2N_2 which must be distributed between the CH_2 and N_2 . Exactly how this energy is distributed in both ketene and diazomethane is not known. However, unimolecular studies of methylcyclopropane isomerization produced by the reaction of 1CH_2 and propene have indicated that there is only a small difference between the lifetimes of methylcyclopropane in the diazomethane system at 436 nm and in the ketene system at 320 nm.³⁴

If we assume that 70% of the energy available from the photolysis of ketene goes into the 1CH_2 ,³⁵ in order for the energies of

34. Dorer, F. H. and Rabinovitch, B. S., J. Phys. Chem. 69, 1952, 1964, 1973 (1965).

35. Based on our experiments with ketene and cyclopropane, see Chapter 5.

$^1\text{CH}_2$ from diazomethane photolyzed at 436 nm and $^1\text{CH}_2$ from ketene at 320 nm to be approximately equal, we must assume that only 20% of the photolysis energy from the diazomethane goes into the $^1\text{CH}_2$. If the fraction of energy does not change with wavelength, $^1\text{CH}_2$ produced from ketene at 277 nm has almost 9 kcal/mole more energy than $^1\text{CH}_2$ produced from diazomethane produced at 405 nm. However, these calculations apply to the addition of $^1\text{CH}_2$ to the C=C double bond in propane which occurs approximately 10 times faster than the insertion of $^1\text{CH}_2$ into a C-H bond.³⁴ By the time $^1\text{CH}_2$ reacts with isobutane, it has undergone ten more collisions than it would have if it were reacting with a C=C double bond and so will be more vibrationally relaxed. Thus, the actual difference between $^1\text{CH}_2$ produced in a ketene-alkane system at 277 nm and $^1\text{CH}_2$ produced in a diazomethane system is less than 9 kcal/mole, and the agreement between our results with ketene at 277 nm, Ho and Noyes's¹¹ results with ketene at 270 nm, and Bell's⁹ results with diazomethane at 405 nm does not appear to be too fortuitous.

A Experimental Results of Other Workers

Eder and Carr⁸ studied the photolysis of a ketene-propane mixture in the presence of various inert gases at 260 nm, 313 nm, and 350 nm and claimed to have found no trend in the $k_{isc}(M)/k_{sprod}$ ratio with photolyzing wavelength. At the longer wavelengths, 330 nm-366 nm, a wavelength dependence is not easy to observe since

most of the $^3\text{CH}_2$ is formed from the ketene via the $^3\text{A}_2$ state of ketene, and only a small fraction of the $^3\text{CH}_2$ is formed from the $^1\text{CH}_2$. There is considerable scatter in Eder and Carr's results which would have hidden a difference between the $k_{\text{isc}}(\text{M})/k_{\text{sprod}}$ ratio at 313 nm and 260 nm if the difference were not large as expected from our data. (The value of the $k_{\text{isc}}(\text{M})/k_{\text{sprod}}$ ratio in some of Eder and Carr's experiments varied by at least 50%.)

Cox and Preston⁶ studied the photolysis of ketene in the presence of various inert gases at 249 nm and 280 nm and found no wavelength dependence in the $k_{\text{isc}}(\text{M})/k_{\text{sprod}}$ ratio. They only looked at the change in the ratio when two gases were added, Xe and N_2 . Only two experiments were done at 280 nm in which Xe was added to the ketene-oxygen mixture and two in which Xe was added to the ketene-carbon monoxide mixture. The least-squares slope of a plot of the reciprocal of the quantum yield of C_2H_4 against the ratio of the concentrations of diluent gas to ketene determined the value of $k_{\text{isc}}(\text{M})/k_{\text{sprod}}$. The error which Cox and Preston report is 40% of the value of the slope for the Xe- O_2 experiments (although it is smaller for other experiments). Thus, any dependence less than 40% could not have been seen. Furthermore, nitrogen reacts with $^1\text{CH}_2$ to form CH_2N_2 ³⁶ and since their experiments measured the total removal of $^1\text{CH}_2$ by N_2 , if the

36. Shilov, A. E., Shteinman, A. A., and Tjabin, M. B., Tet. Letters 39, 4177 (1968).

associated rate constant is comparable to that for the intersystem crossing reaction, any trend of the intersystem crossing reaction with wavelength could easily be masked by the reaction to form CH_2N_2 .

Koob, et al.³⁷ used an entirely different source of methylene, the vacuum ultra-violet photolysis of cyclopropane and propane. They claimed to find no wavelength dependence in the rate of the intersystem crossing reaction. However, less is known about the decomposition of these molecules and a comparison between their systems and the ketene system may not be valid because the distribution of energy in these larger molecules is even less well known than in the simpler ketene or diazomethane molecules.

B Summary of Arguments for Energy Dependence in the Rate of Intersystem Crossing

Although the ratio of the intersystem crossing rate to the reaction rate has been determined in this work at only a few wavelengths, our experiments suggest that there may be an energy dependence in this ratio. The largest change in the intersystem crossing rate relative to the value at 277 nm occurs when 214 nm is

37. Dhingra, A. K. and Koob, R. D., J. Phys. Chem. 74, 4490 (1970); Dhingra, A. K., Vorachek, J. H., and Koob, R. D., Chem. Phys. Letters 9, 17 (1971); Koob, R. D., J. Chem. Phys. 73, 3068 (1969).

used, but we are reluctant to give much weight to the value of the $k_3/(k_1+k_2)$ ratio at this wavelength for reasons to be discussed in the next section. Experiments by other workers have indicated that the intersystem crossing is not a function of the energy of the $^1\text{CH}_2$, however, as discussed above, their data are such that an absence of an energy dependence can not be proven. The theory of bimolecular intersystem crossing can explain an increase in the rate of crossing with an increase in the energy of the $^1\text{CH}_2$, and so, all that really can be said is that an energy dependence in the intersystem crossing rate for methylene cannot be very large if it exists, but that experiments have not shown its absence. A determination of whether or not there is such a dependence must wait for more accurate experiments, ideally in a less complicated system than ours.

VII The Photolysis of Ketene at 214 nm

The results of our experiments at 214 nm have been referred to but, so far, they have not been discussed in any detail. As shown in Table 3-III and figure 3-1, except for the experiments at 214 nm, as the photolyzing energy increases, both the measured percent of $^3\text{CH}_2$, $^3\text{CH}_2\text{-O}_2$, and the neopentane to isopentane ratio decrease. The $^3\text{CH}_2\text{-O}_2$ and the ratio of neopentane to isopentane are both larger at 214 nm than expected from the trends in both at the longer wavelengths. The quantum yield of $^1\text{CH}_2$, ϕ_s , as determined from the

CO experiments (see Table 4-VI) approaches 1.0 as the photolyzing energy increases. At 214 nm, $\phi_s = 1.0$ as anticipated from this trend with photolyzing wavelength. If the experiments with O_2 have correctly measured 3CH_2 as 48% of the total methylene and if $\phi_s = 1.0$, this must mean that at 214 nm the ratio of $k_3/(k_1+k_2)$ is almost twice as large as at 277 nm or 313 nm (see Table 4-IV). But if the rate of intersystem crossing from 1CH_2 were twice as large at 214 nm, then the pentane yields in the presence of large concentrations of CO should be smaller than at 277 nm since the amount of 1CH_2 reacting with isobutane would be smaller. As seen in Table 3-I and figures 3-3, 3-4, and 3-5, this is not the case; the pentane yields are almost the same at 214 nm and 277 nm. Thus, since an increase in the rate of intersystem crossing cannot explain these results, an examination of the difference between the absorption spectrum of ketene in this region and at other wavelengths may give a clue to the explanation.

As described earlier (pages 117-121), the absorption of radiation at 214 nm excites ketene from the 1A_1 ground state to the 1A_1 second excited singlet state. A priori, ketene in the 1A_1 excited state would be expected to dissociate to either $CH_2(^1A_1)$ and $CO(^1\Sigma)$ or $CH_2(^1B_1)$ and $CO(^1\Sigma)$. At 214 nm, 56 kcal/mole of energy (the energy in excess of the amount needed to decompose the ketene) is available to the 1A_1 which may be distributed between the two products, CH_2 and CO , differently when the 1A_1

state dissociates than when the 1A_2 (the first excited singlet) state of ketene dissociates. As can be seen from figure 4-2b, this is enough energy to reach the 1B_1 state (the second excited singlet state) of methylene even if CO also gets some of the energy (the vibrational frequency of CO is 2174 cm^{-1} , or 6.2 kcal/mole). The 1B_1 state of methylene has almost the same configuration as the 3B_1 state (Table 1-I). Although $\text{CH}_2({}^1B_1)$ is a singlet, unlike $\text{CH}_2({}^1A_1)$, its electrons are not paired. Thus, if $\text{CH}_2({}^1B_1)$ is formed, some of its reactions might be similar to the reactions of $\text{CH}_2({}^3B_1)$. The likely presence of $\text{CH}_2({}^1B_1)$ and its reactions with O_2 , CO, and C-H bonds can explain the anomalies in the results of the photolysis of ketene at 214 nm.

A The Reaction of $\text{CH}_2({}^1B_1)$ with Isobutane

As we have mentioned in the introduction, Chapter 1, the reactions of $\text{CH}_2({}^1B_1)$ have not been studied experimentally. Hoffmann's calculations of the reaction paths of methylenes³⁸ indicate that the concerted reaction of the 1A_1 state is based on the availability of the unfilled p orbital rather than on the singlet character of the methylene. The 1B_1 state does not have an unfilled p orbital and so cannot react via the same pathway as the 1A_1 state does. Since the spatial arrangement of the electrons seems

38. Hoffmann, R., J. Am. Chem. Soc. 90, 1475 (1968); Dobson, R. C., Hayes, D. M., and Hoffmann, R., *ibid* 93, 6188 (1971).

to be the important factor in this type of reaction, it is more likely that the 1B_1 state reacts similar to the 3B_1 state than to the 1A_1 state. Thus, $CH_2(^1B_1)$ would be expected to abstract a H atom from the C-H bonds and thus must have the same relative preference for the tertiary C-H bonds as $CH_2(^3B_1)$ does. Once we have made this assumption, we must conclude from the oxygen and carbon monoxide experimental results that the $CH_2(^1B_1)$ reaction with isobutane has been eliminated or else the neopentane to isopentane ratio would not have been 0.14-0.15 in both O_2 and CO.

B The Reaction of $CH_2(^1B_1)$ with O_2

If the reaction of $CH_2(^3B_1)$ is very fast compared to the reaction of $CH_2(^1A_1)$ with O_2 because of the presence of unpaired electrons in $CH_2(^3B_1)$ and not because of its triplet nature, the reaction of O_2 with $CH_2(^1B_1)$ should also be faster than with $CH_2(^1A_1)$. This would not be unexpected since the reactions of O_2 with CH_3 and other radicals with an unpaired electron are fast.³⁹ If the reaction of O_2 with $CH_2(^1B_1)$ is fast, then the percent of 3CH_2 measured by the O_2 experiments could actually be a measure of both $CH_2(^1B_1)$ and $CH_2(^3B_1)$.⁴⁰

39. See, for example, van den Bergh, H. E. and Callear, A. B., *Trans. Faraday Soc.* 67, 2017 (1971).

40. Of course, one must remember that in these experiments only a few percent of O_2 is present so that the $CH_2(^3B_1)$ and $CH_2(^1B_1)$ (continued)

Unfortunately, neither in this work at 214 nm nor in that of Kistiakowsky and Walter³³ was the concentration of oxygen systematically varied. Thus, there is no unequivocal experimental evidence on which an estimate of the extent of the reaction of O_2 with the methylene produced at 214 nm can be made. We will come back to this point a little later in the discussion, but for now, because of the assumption already made about the reaction of $CH_2(^1B_1)$ with isobutane, we must assume that the reaction of O_2 with $CH_2(^1B_1)$ is relatively fast.

C The Reaction of $CH_2(^1B_1)$ with CO

The reaction of $CH_2(^3B_1)$ with $CO(^1\Sigma)$ is faster than with isobutane. This has been attributed to the formation of the fairly stable 3A_2 state of ketene thus removing $CH_2(^3B_1)$ from the reaction system.^{12,19} The reaction of $CH_2(^1B_1)$ with $CO(^1\Sigma)$ is not expected to be faster than the reaction with isobutane since $CH_2(^1B_1)$ and $CO(^1\Sigma)$ undoubtedly correlates with an unbound state of ketene as $CH_2(^1A_1)$ does. (The bands in the 180 nm-200 nm region are diffuse which suggests strong predissociation of the excited 1A_1 state.) If the $CH_2(^1B_1)$ does not react faster with CO than with isobutane,

40. (cont'd,) react with O_2 much faster than with isobutane and the $CH_2(^1A_1)$ reacts with isobutane faster than with O_2 . Thus, O_2 removes $CH_2(^3B_1)$ and $CH_2(^1B_1)$ but only a very small percent of $CH_2(^1A_1)$. See, also, page 110.

the ϕ_s measured by the CO experiments might be larger than that expected from the measured ${}^3\text{CH}_2\text{-O}_2$, (if k_1 , k_2 , and k_{13} are not very different with $\text{CH}_2({}^1\text{B}_1)$ than with $\text{CH}_2({}^1\text{A}_1)$) because the ϕ_s would be a measure of both $\text{CH}_2({}^1\text{A}_1)$ and $\text{CH}_2({}^1\text{B}_1)$, i.e., of all the methylene present after the ${}^3\text{B}_1$ state has been removed by reaction with CO. However, if the $\text{CH}_2({}^1\text{B}_1)$ were not removed by reaction with CO, the neopentane to isopentane ratio in the presence of more than 60 Torr of CO would be larger than 0.14-0.15 because the $\text{CH}_2({}^1\text{B}_1)$ is expected to react with C-H bonds as $\text{CH}_2({}^3\text{B}_1)$ does. This was not found to be true experimentally.

The addition of at least 60 Torr of CO more than doubles the total pressure of the reaction mixture compared to the standard mixture of 50 Torr of isobutane, 5 Torr of ketene, and 0.5 Torr of propane. This increase in pressure compared to the experiments without CO may cause methylene in the ${}^1\text{B}_1$ state to relax to the ${}^1\text{A}_1$ state because of the increase in the number of collisions $\text{CH}_2({}^1\text{B}_1)$ experiences before it can react with isobutane. An internal conversion from $\text{CH}_2({}^1\text{B}_1)$ to $\text{CH}_2({}^1\text{A}_1)$ is expected to be quite fast since there is no change in multiplicity. Thus, the addition of enough CO to remove any $\text{CH}_2({}^3\text{B}_1)$ probably also converts most of the $\text{CH}_2({}^1\text{B}_1)$ to the lower energy $\text{CH}_2({}^1\text{A}_1)$. Only $\text{CH}_2({}^1\text{A}_1)$ would then be present to react with the isobutane. If ϕ_s is 1.0 under these conditions, the most likely explanation is that only CH_2 in the ${}^1\text{B}_1$ state is formed by the photodecomposition

TABLE 4-III

A Summary of CH₂ Reactions

Rate of Reaction Compared to the Rate of CH ₂ + alkane	State of CH ₂		
	¹ A ₁	³ B ₁	¹ B ₁
CH ₂ + O ₂	slow	fast	fast
CH ₂ + ketene	slow	fast	slow ^a
CH ₂ + CO	slow	fast	slow
¹ B ₁ → ¹ A ₁ , internal conversion by collisions	----	----	same
with alkane			

a) Based on the data of Kistiakowsky and Walter, reference 33.

of ketene at 214 nm and it has been converted by collisions with CO and isobutane, to $\text{CH}_2(^1\text{A}_1)$.

Thus, starting with the assumption that $\text{CH}_2(^1\text{B}_1)$ reacts with isobutane to abstract H from C-H bonds, in the same way that $\text{CH}_2(^3\text{B}_1)$ does, our experimental results are consistent with the following description of the photolysis of ketene at 214 nm. The photo-decomposition of ketene at 214 nm produces only $\text{CH}_2(^1\text{B}_1)$ and $\text{CO}(^1\Sigma)$. The $\text{CH}_2(^1\text{B}_1)$, with the aid of collisions, can be converted into $\text{CH}_2(^1\text{A}_1)$ and $\text{CH}_2(^3\text{B}_1)$. The internal conversion (via collisions) is undoubtedly the faster reaction since there is no change in multiplicity and since a $\text{A}_1 \longleftrightarrow \text{B}_1$ transition is allowed by the C_{2v} symmetry of methylene. In the presence of more than 60 Torr of CO (a total pressure of more than 115 Torr), the reaction of $\text{CH}_2(^1\text{B}_1)$ with isobutane has been eliminated because the $\text{CH}_2(^1\text{B}_1)$ has been converted to $\text{CH}_2(^1\text{A}_1)$. In the presence of O_2 , the reactions of $\text{CH}_2(^1\text{B}_1)$, and of any $\text{CH}_2(^3\text{B}_1)$ that has been formed from the intersystem crossings of CH_2 either in the $^1\text{A}_1$ state or the $^1\text{B}_1$ states with isobutane have been suppressed because of the relatively fast reaction of $\text{CH}_2(^1\text{B}_1)$, and $\text{CH}_2(^3\text{B}_1)$, with O_2 .

D Other Possibilities

Suppose the reaction of $\text{CH}_2(^1\text{B}_1)$ with isobutane did not involve the abstraction of H from C-H bonds, but that $\text{CH}_2(^1\text{B}_1)$ reacted

somewhat like $\text{CH}_2(^1\text{A}_1)$, i.e., concertedly and with no preference for either type of C-H bond. In this case, the reaction of O_2 with $\text{CH}_2(^1\text{B}_1)$ must be slower than the reaction with isobutane. If it were faster, the neopentane to isopentane ratio would not agree with the percent of $^3\text{CH}_2$ measured by the oxygen experiments.

(See figure 3-2.) The oxygen experiments would then imply that the rate of intersystem crossing from methylene in the $^1\text{B}_1$ state to the $^3\text{B}_1$ state must be about twice as fast as from the $^1\text{A}_1$ state.

(See Table 4-II.) The $^1\text{B}_1 \rightarrow ^3\text{B}_1$ crossing is expected to be faster than that of $^1\text{A}_1 \rightarrow ^3\text{B}_1$ because of the vibrational spacing arguments described previously (page 132). The reaction of CO with both $\text{CH}_2(^1\text{B}_1)$ and $\text{CH}_2(^1\text{A}_1)$ must again be slower than that with isobutane.

Since the pentane yields in the CO experiments are almost equal at 214 nm and 277 nm, if ϕ_g is still equal to 1.0, then the rate of reaction of $\text{CH}_2(^1\text{B}_1)$ with CO must be even slower than the reaction of $\text{CH}_2(^1\text{A}_1)$ with CO. (See equations 3-3 and 3-4.) However, if the intersystem crossing rate from the $^1\text{B}_1$ state is relatively fast, it is unlikely that the internal conversion, via collisions, to the $^1\text{A}_1$ is not even faster. Thus, it would be hard to believe that in the concentrations of CO used any significant amounts of $\text{CH}_2(^1\text{B}_1)$ remain. The presence of $\text{CH}_2(^1\text{A}_1)$ that is highly vibrationally excited cannot be completely ruled out as contributing to a larger yield of pentanes in the CO experiments, but in the presence of large concentrations of CO, this does not seem that likely. (The

point here being that the efficiency of the reaction of $\text{CH}_2(^1\text{A}_1)$ with CO is small enough so that collisions with CO will either take away most of the vibrational energy of the $\text{CH}_2(^1\text{A}_1)$ or else convert it to $\text{CH}_2(^3\text{B}_1)$.)

A third possibility is that $\text{CH}_2(^1\text{A}_1)$ as well as $\text{CH}_2(^1\text{B}_1)$ is produced at 214 nm. This is not impossible since the unbound states correlating to $\text{CH}_2(^1\text{B}_1)$ and $\text{CH}_2(^1\text{A}_1)$ probably both cross the $^1\text{A}_1$ bound state (see figure 4-2a). However, the experimental evidence to date does not warrant this more sophisticated picture.

It is apparent that further experiments with O_2 and also with different gases, such as Xe, Ar, and CF_4 , would be very useful in describing the ketene photolysis at 214 nm.

VIII Summary of Conclusions

The results of our experiments with the photolysis of a ketene-isobutane mixture at several wavelengths can only be explained by assuming that there are three different electronic species of methylene which can be formed. At wavelengths longer than 320 nm, most of the ground state of methylene, $\text{CH}_2(^3\text{B}_1)$, results from the decomposition of the $^3\text{A}_2$ state of ketene. The $^3\text{A}_2$ state of ketene is formed from the absorption, by the $^1\text{A}_1$ ground state, of radiation longer than 320 nm. At wavelengths shorter than 320 nm, most of the $\text{CH}_2(^3\text{B}_1)$ is formed by the collision-induced intersystem crossing of methylene in the first excited singlet state, $\text{CH}_2(^1\text{A}_1)$. This intersystem crossing rate may depend on the energy of the $\text{CH}_2(^1\text{A}_1)$. In the region around 277 nm (250 nm-290 nm), only $\text{CH}_2(^1\text{A}_1)$ is formed from the photodecomposition of ketene; any $\text{CH}_2(^3\text{B}_1)$ present is a result of the intersystem crossing from $\text{CH}_2(^1\text{A}_1)$. At the shortest wavelength studied, 214 nm, the photolysis of ketene produces methylene in the second excited state, $\text{CH}_2(^1\text{B}_1)$. The $\text{CH}_2(^1\text{B}_1)$ behaves as the $\text{CH}_2(^3\text{B}_1)$ does in its reactions with O_2 and alkanes. Presumably this is because the spatial distribution of the electrons is the same in both B_1 states.

The technique of using CO to remove the $\text{CH}_2(^3\text{B}_1)$ can be used to measure the quantum yield of $\text{CH}_2(^1\text{A}_1)$, ϕ_s , at wavelengths longer than about 250 nm, but it cannot be used to measure ϕ_s in the 214 nm

region where $\text{CH}_2(^1\text{B}_1)$ is produced because $\text{CH}_2(^1\text{B}_1)$ does not react as $\text{CH}_2(^3\text{B}_1)$ does with CO. The collision-induced internal conversion of $\text{CH}_2(^1\text{B}_1)$ to $\text{CH}_2(^1\text{A}_1)$ is faster than the collision-induced intersystem to $\text{CH}_2(^3\text{B}_1)$.

Results and Discussion of the Cyclopropane Experiments

Results

$^1\text{CH}_2$ inserts into the C-H bonds of cyclopropane to form energy-rich methylcyclopropane. The fate of the excited methylcyclopropane is decided according to the following scheme.^{1,2,3,4}

The overall rate of the decomposition of methylcyclopropane, k_a , is equal to the collision frequency, ω , multiplied by the ratio of the products from decomposition, D , to the products from collisional stabilization, S ,

$$k_a = \omega \left(\frac{D}{S} \right)$$

-
1. Butler, J. N. and Kistiakowsky, G. B., J. Am. Chem. Soc. 82, 759 (1960).
 2. Setser, D. W. and Rabinovitch, B. S., *ibid* 86, 564 (1964).
 3. Dorer, F. H. and Rabinovitch, B. S., J. Phys. Chem. 69, 1952, 1964, 1973 (1965).
 4. Chesick, J. P., J. Am. Chem. Soc. 82, 3277 (1960).

The sum of the decomposition products is the sum isobutene + butene-1 + cis-butene-2 + trans-butene-2 and, of course, methylcyclopropane is the product of collisional stabilization. The reciprocal of k_a is the lifetime of the excited methylcyclopropane. The rate constant for the decomposition of excited methylcyclopropane is the slope of the plot of D/S versus ω^{-1} or $1/(\text{total pressure})$ since the frequency of the gas kinetic collisions is proportional to the total pressure of the gas.

The insertion of $^1\text{CH}_2$ into cyclopropane was studied at four wavelengths, 214 nm, 277 nm, 313 nm, and 330 nm. Oxygen (5% of the total pressure) was added to the photolysis mixture to ensure that both $\text{CH}_2(^3\text{B}_1)$ and $\text{CH}_2(^1\text{B}_1)$, $^3\text{CH}_2$, were substantially eliminated from the reaction system. Plots of D/S versus $1/\text{total pressure}$ were made for each wavelength and are shown in figure 5-1. The k_a 's calculated from these plots for the cyclopropane-ketene mixtures are presented in Table 5-V along with the k_a determined by Dorer and Rabinovitch³ from their propylene-ketene system at 320 nm. As expected, the k_a 's increase as the photolyzing energy increases. The inversion Butler and Kistiakowsky observed in their experiments, in which $^3\text{CH}_2$ was not eliminated, is not present in this series of experiments.

The butene-1 and isobutene were not resolved on the chromatograph and thus a detailed study of the isomer distribution could not be made. The problems in resolution have already been described in the chapter on apparatus and techniques. Other workers have not shown any startling trends in the isomer distribution with changes in the energy of the excited methylcyclopropane over the pressure region we studied, and so none were expected here. The ratio of the yields of trans-butene-2 to cis-butene-2 and the ratio of the sum of the yields of the butenes-2 to the sum of the yields of the isobutene and butene-1 yields were measured. These ratios are included among the results listed in Table 5-I. As a general trend, both ratios decrease slightly as the total pressure of the system increases. Butler and Kistiakowsky¹ observed a similar trend.

When the total pressure was large, the methylcyclopropane was the major product and the methylcyclopropane peak was the dominant peak. Cis- and trans-butene-2 were the last of the products to be eluted from the column and thus had the broadest peaks. When the pressure was large, all of the butene peaks were small, but the butenes-2 peaks were the broadest and therefore the hardest to measure accurately. The smaller value of the ratio of butenes-2 to the sum of isobutene and butene-1 at larger pressures is probably due to the increase in the error of the butene-2 peak area measurements.

* MCP is methylcyclopropane.
cis-butene-2.

** the ratio of trans-butene-2 to

The decrease in the ratio of trans-butene-2 to cis-butene-2 as the pressure increases results from a small amount of the cis-butene-2 isomerizing to trans-butene-2 at low pressures. This is discussed in greater detail in a later section.

An Introduction to Previous Work on the Decomposition of Methylcyclopropane

Dorer and Rabinovitch³ have studied the isomerization of several cyclopropanes including methylcyclopropane. They formed the methylcyclopropane by reacting propylene with methylene which was produced by the photolysis of ketene at 320 nm or the photolysis of diazomethane at 435 nm. They were unable to resolve the isobutene products, and so estimated the yield from Butler and Kistiakowsky's¹ data. Dorer and Rabinovitch³(DR) constructed a set of models for the isomerization of methylcyclopropane which they claim fit Setser and Rabinovitch's data for the thermal isomerization of 1,2-dideutero-3-methylcyclopropane.² DR used these models to fit the overall isomerization rate of methylcyclopropane, k_a , for the addition of $^1\text{CH}_2$ to propylene. These models were used for $^1\text{CH}_2$ produced from diazomethane and from ketene. The construction of these models was based on the results of Setser and Rabinovitch's (SR) work with CH_2 additions to ethylene and butene-2.⁵

5. Setser, D. W. and Rabinovitch, B. S., Can. J. Chem. 40, 1425 (1962).

Setser and Rabinovitch⁵ studied the addition of methylene to ethylene. The methylene was generated by the thermal decomposition of diazomethane in the range from 225°C to 450°C and the photolyses of diazomethane at 456 nm and ketene at 320 nm. They constructed their cyclopropane models to fit the thermal isomerization results of cyclopropane⁶ and then used these models to determine an average energy, $\langle E \rangle$, for the excited complexes produced from each methylene source. The $\langle E \rangle$'s obtained by this method fit the thermochemical values, but several of the heats of formation they used are now known to be wrong. DR used the $\langle E \rangle$ calculated by SR for cyclopropane, i. e., an $\langle E \rangle$ of about 110 kcal/mole, but corrected this $\langle E \rangle$ to account for the extra methyl group in methylcyclopropane. DR constructed their models so that their experimental rate constants for CH_2 generated from diazomethane corresponded to an $\langle E \rangle$ of 108 kcal/mole and also gave a "good fit" to the thermal isomerization results of Setser and Rabinovitch².

The rate constants, k_a , which we determined for the ketene and cyclopropane system are all larger than the rate constants determined by DR for diazomethane and cyclopropane ($k_a = 9.7 \times 10^8 \text{ sec}^{-1}$).

6. Falconer, W. E., Hunter, T. E., and Trotman-Dickenson, A. F., J. Chem. Soc. 1962, 609; Pritchard, H. O., Sowden, R. G., and Trotman-Dickenson, A. F., Proc. Roy. Soc. A217, 563 (1953); Schlag, E. W. and Rabinovitch, B. S., J. Am. Chem. Soc. 81, 5996 (1960).

Therefore, the average energies, $\langle E \rangle$'s, of our methylcyclopropane are expected to be larger than 108 kcal/mole. At this point, it is important to check the thermochemistry of our ketene-cyclopropane system to be sure that the $\langle E \rangle$'s can be larger than 108 kcal/mole.

The insertion of CH_2 into the C-H bonds of cyclopropane to form methylcyclopropane is 99.2 kcal/mole exothermic when both reactants have no energy in excess of their thermal energy. The photolysis of ketene at 330 nm has 10.2 kcal/mole more energy than required to decompose ketene (76.4 kcal/mole). If all of this energy went into the methylene and if the methylene did not lose energy before reacting with cyclopropane, the $\langle E \rangle$ for methylcyclopropane would be 109.4 kcal/mole; this is referred to as the $\langle E \rangle_{\text{max}}$ at 330 nm. Thus for our smallest rate constant, $\langle E \rangle$ cannot be larger than 109 kcal/mole. This is just larger than the 108 kcal/mole DR find for the $\langle E \rangle$ of methylcyclopropane produced in their diazomethane-propylene system at 436 nm. The $\langle E \rangle_{\text{max}}$ for each wavelength we have studied with our ketene-cyclopropane system is listed in Table 5-V along with the k_a measured at that wavelength. Also included in Table 5-V is the $\langle E \rangle_{\text{max}}$ for the ketene-propylene system at 320 nm studied by DR, their experimental rate constant, k_a , and the k_a found by Chesick⁴ at large pressures, k_w in his studies of the thermal isomerization of methylcyclopropane.

When we first started these experiments, the newest heat of formation of ketene, -11.4 ± 0.4 kcal/mole, had not appeared in the literature,⁷ and the $\langle E \rangle_{\max}$ for each wavelength was 4 kcal/mole smaller than listed in Table 5-IV. This meant that at the longest wavelength we used, 330 nm, and also for DR's photolysis of ketene and propylene at 320 nm, the $\langle E \rangle$'s calculated with DR's published model were larger than $\langle E \rangle_{\max}$. In order to resolve this difficulty, we constructed a number of different models which were modifications of DR's models, and we also tried several new models. These models are described in Table 5-III. The results of the calculations for each model are presented in Table 5-IV. Table 5-II describes the frequencies in the methylcyclopropane molecule.

The model DR published, ignoring the methyl torsion of the methyl group attached to the ring, complex 3 in Table 5-II but with $E_0 = 61.4$ kcal/mole, gives the following parameters:

1) at $T = 298^\circ\text{K}$, $\log A = 14.34$ and $E_a = 62.1$ kcal/mole,

at $T = 720.1^\circ\text{K}$, $\log A = 14.92$, $E_a = 63.4$ kcal/mole and

$$k_\omega = 0.472 \times 10^{-4} \text{ sec}^{-1},$$

at $T = 763.8^\circ\text{K}$, $\log A = 14.97$, $E_a = 63.6$ kcal/mole and

$$k_\omega = 5.98 \times 10^{-4} \text{ sec}^{-1},$$

7. Nuttal, R. L., Laufer, A. H., and Kilday, M. V., J. Chem. Thermodynamics **3**, 167 (1971).

and

- 2) the $\langle E \rangle$'s for the ketene systems are
 102.5 kcal/mole for propylene at 320 nm (DR's results) and
 107.1, 108.0, 109.7, and 112.5 kcal/mole for cyclopropane
 at 330 nm, 313 nm, 277 nm, and 214 nm, respectively.

The Applicability of the Strong Collision Assumption

The RRKM theory (and most other unimolecular theories) assumes that each gas kinetic collision of the excited complex is strong enough to deactivate it. Any decomposition of the complex must occur, therefore, before the first collision. This strong collision assumption was used to calculate the lifetimes of the methylcyclopropane from the plot of the ratio of the yields, butenes/methylcyclopropane, versus the reciprocal of the pressure of the system. The decomposition rate constants are about $2 \times 10^9 \text{ sec}^{-1}$. At 100 Torr, the collision frequency, ω , of methylcyclopropane in cyclopropane is 1.4×10^9 collisions/sec, which is of the same order of magnitude as k_a . DR's value of k_a is $0.72 \times 10^9 \text{ sec}^{-1}$ for their ketene-propylene system at 320 nm, which implies, in the most simplistic view, that at about 100 Torr, the methylcyclopropane will be hit twice before it decomposes.

Other workers⁸ have shown that in similar systems, i.e., where $\langle E \rangle$ is about 100 kcal/mole, each collision deactivates the excited molecule or complex by at least 30 kcal/mole. The critical energy for methylcyclopropane isomerization is about 60 kcal/mole. Thus, it is possible that one collision will be sufficient to take away enough energy so that the resulting energy of the methylcyclopropane is less than 60 kcal/mole.⁹ As the pressure increases to the point where there are one or more collisions during the lifetime of the excited complex, the average energy of the complex will decrease, and so, k_a will become smaller. Evidence for this effect is seen in the upward curvature in figure 5-1; the ratio of the yields of the butenes/methylcyclopropane is larger at small pressures.

An Estimate of the Rate of Reaction of $^1\text{CH}_2$ with Cyclopropane

There is a decided difference between the lifetimes of the methylcyclopropane produced at the different wavelengths used which must reflect the difference in energies carried into the methyl-

9. Using model 7 of Tables 5-III and 5-IV, if 30 kcal/mole is subtracted from $\langle E \rangle$ for 313 nm, the k_f will decrease from $0.185 \times 10^{10} \text{ sec}^{-1}$ to $0.117 \times 10^{10} \text{ sec}^{-1}$. Thus, after the complex loses 30 kcal/mole of energy, the k_f of the complex will be so much smaller that it is even more likely to be hit again before decomposing. This is effectively a strong collision situation.

Tables 5-III and 5-IV describe some of the models tried and the experimental parameters obtained using these models in the RRKM theory. Table 5-III lists the molecular frequencies, the frequencies changed in the complex, and the E_0 (the critical energy for isomerization). Table 5-IV is the result of the calculations and lists the average energy, $\langle E \rangle$, of the complex produced at each wavelength, and the thermal rates predicted by these models. As described in the text, model 7 is the best fit.

$$k_{\infty} = 6.79 \times 10^{-4} \quad \text{at } 763.8^\circ\text{K}$$

* k_a was determined from $w(\frac{D}{S}) = k_a$. $\sigma = 5.4 \text{ \AA}$ was used in calculating w .

** k_a was determined by Dorer and Rabinovitch. Although the error bounds are not given for the overall decomposition rate constant, the error for the decomposition to the individual isomers is given as $\pm 25\%$.

cyclopropane by the $^1\text{CH}_2$. At lower pressures (pressures less than 100 Torr), there is still a difference in the lifetimes even when the difference in photolyzing energy is only 5 kcal/mole and the excess energy available to the CH_2 is 5 and 10 kcal/mole, at 330 nm and 313 nm. If $^1\text{CH}_2$ collided with the cyclopropane without reacting, at least some of its energy would be carried off by the cyclopropane which is relatively efficient in transferring vibrational energy. CH_2 has fewer vibrational degrees of freedom than methylcyclopropane and so collisions between CH_2 and cyclopropane are likely to be less efficient in transferring vibrational energy than collisions between methylcyclopropane and cyclopropane. Even though the collisions of methylene will be less efficient than those of methylcyclopropane, if the collisions of methylcyclopropane transfer 30 kcal/mole to the cyclopropane, it is hard to imagine that the collisions of methylene will transfer less than a few kcal/mole. The difference in lifetimes at 313 nm and 330 nm means that the CH_2 must not have lost much energy by collisions before it reacts and, therefore, it must react within one or two collisions.

Modifications of Dorer and Rabinovitch's Models

If DR's models are modified by assuming there are fewer oscillators actively involved in the methylcyclopropane complex, or more specifically, that some of the CH stretches of the CH_2 groups in the ring do not contribute to breaking the cyclopro-

pane ring and, thus, do not contribute to the distribution of the total energy of the complex or molecule, the $\langle E \rangle$'s calculated for the k_a 's are significantly reduced. Only one model with such a modification is shown in Tables 5-III and 5-IV, model 4, although several others were also tried.

Reducing the degrees of freedom in the model will also change the shape of the "thermal fall-off" curve. The isomerization rate constant, k , is calculated for thermal isomerization at several temperatures and several pressures. The high pressure limit of k is k_∞ . At each temperature, the log of k/k_∞ is plotted against the log of the pressure, and this plot is referred to as the "thermal fall-off" curve. This curve is a convenient way to help judge the applicability of the models constructed. Reducing the number of oscillators by ignoring the CH ring stretches results in a sharper "fall-off", i.e., a faster decrease in the ratio of k/k_∞ with decreasing pressure. This comparison was used in discarding some of the models, but the plots are not shown since describing too many models would have obscured the more significant ones. Figures 5-2 and 5-3 depict some of the "thermal fall-off" curves for some of the models tried.

Despite these improvements, reducing the degrees of freedom in the complex is not really a satisfactory approach for several reasons. The RRKM theory should be able to predict the correct

behavior without assuming that certain vibrations are not involved. The isomerization of cyclopropane has been successfully described by the RRKM theory with a model which includes all of the vibrations of the molecule.¹⁰ Of course, the cyclopropane studies were thermal isomerizations, and the methylcyclopropane lifetimes in our chemical activation system are much shorter (10^{-10} to 10^{-9} sec) than in the thermal system (8×10^{-7} sec, Chesick⁴), so it is possible that the energy has not had a chance to be distributed among all the modes. However, the distributions of butene isomers were as anticipated from the pre-exponential factors which implies that the energy has been fairly well distributed among most of the modes. Butler and Kistiakowsky¹ found no difference in the distribution of the isomers between their cyclopropane and propylene system which meant that the energy flow in the excited methylcyclopropane in their systems was fast enough to completely distribute the energy among all the vibrational modes of the complex. Thus, since the thermal system can be described by a model which involves all of the vibrations, the chemical activation system must also be described with the same model. According to the RRKM theory, even those vibrations which are not directly involved in the reaction coordinate will contribute to the energy density of both the molecule and the complex.

10. Wieder, G. M. and Marcus, R. A., J. Chem. Phys. 37, 1835 (1962); Lin, M. C. and Laidler, K. J., Trans. Faraday Soc. 64, 927 (1968).

The sometimes used argument¹¹ that vibrations of a symmetry different from that of the reaction coordinate are not involved in the free flow of energy between modes and, therefore, are not involved in the distribution of the total energy of the molecule seems to be especially weak in cyclopropane isomerizations. The isomerization of methylcyclopropane to any of the butenes involves motions of the atoms which destroy the only symmetry element, the σ_v , of methylcyclopropane. Therefore, both the Λ' and Λ'' vibrations should be equally effective in distributing energy in the transition state.

A second type of modification was tried for DR's model. We "tightened" and "loosened" (increased and decreased the frequencies of) the vibrations DR assumed to be changing during the transition of the methylcyclopropane molecule to the complex. Of DR's models (Tables 5-III and 5-IV, complexes 1, 2, 3, and 4), the looser models fit the thermal fall-off curves better (see figures 5-2 and 5-3) and also, using our experimental rate constants, predict smaller $\langle E \rangle$'s for the excited methylcyclopropane than the tighter models.

The tighter models, in addition to not fitting the thermal data as well as the loose models and predicting larger $\langle E \rangle$'s for

11. The symmetry argument is described by Gill, E. K. and Laidler, K. J., Proc. Roy. Soc. A250, 121 (1959).

methylcyclopropane than the thermochemical maximum, $\langle E \rangle_{\max}$, also predict difference in $\langle E \rangle$ between the ketene-cyclopropane (313 nm) system and the ketene-propylene (320 nm) system which are smaller than expected. The difference in photon energies of the photolyzing wavelengths is 2.1 kcal/mole and the difference in heats of reaction is 7.8 kcal/mole.¹² Thus, the difference in $\langle E \rangle$'s between these two systems should be 9.9 kcal/mole if all the extra photolysis energy is carried by the $^1\text{CH}_2$ to the methylcyclopropane. Since the addition of $^1\text{CH}_2$ to C=C double bonds is faster than the insertion of $^1\text{CH}_2$ into C-H bonds,¹³ it is possible that in the ketene-propylene system, the $^1\text{CH}_2$ suffers no collisions before reacting with propylene. If this is the case, and if the $^1\text{CH}_2$ reaction with cyclopropane occurs after one non-reacting collision which, however, causes the $^1\text{CH}_2$ to lose some energy, the difference in $\langle E \rangle$'s between the ketene-propylene system at 320 nm and the ketene-cyclopropane system at 313 nm may be somewhat less than 9.9 kcal/mole.

Eliminating two of the ring CH stretches (cf. complexes 3 and 4) results in lower $\langle E \rangle$'s but, also, in smaller differences between the $\langle E \rangle$ in the ketene-propylene system at 320 nm and the

12. ΔH_f° at 298°K is given in Benson, S. W., Thermochemical Kinetics, John Wiley and Sons, Inc., New York. (1968) for most of these molecules. See Table 5-VIII.

13. See the review articles, e. g., Bell, J. A., *Prog. Phys. Org. Chem.* 2, 1 (1964) and also reference 3.

Figures 5-2 and 5-3 are the "thermal fall-off" curves at two of Chesick's temperatures. The pressures are in cm of Hg. The figures include Chesick's data at those temperatures and the constants calculated from the RRKM theory using several different models including Dorer and Rabinovitch's published model.

Figure 5-2

Figure 5-3

< E > in the ketene-cyclopropane system at 313 nm. Thus, a new model, looser than DR's model, which fits the characteristics of the thermal isomerization and which is consistent with the thermochemistry of the chemical activation systems is needed.

New Models

There are four different products of methylcyclopropane isomerization and a total, overall reaction path degeneracy of 10. Each of the butene products is the result of the breaking of one C-C single bond in the cyclopropane ring, the formation of a C=C double bond, the breaking of one C-H bond, the transferring of the H to a different carbon atom, and the formation of a new C-H bond. In constructing the models, the details of the breaking and the forming of the different bonds was ignored.

The ideal approach would have been to construct a complex for each of the four pathways and then take a weighted average of the rates of decompositions from the four different complexes to describe the overall decomposition of the methylcyclopropane. However, since the isobutene and butene-1 are not well resolved from each other, it did not seem worthwhile to take this detailed approach. Instead, we constructed four models by estimating the increase in bond lengths necessary for each separate product and

took an average of the bonds in these models which we weighted by the degeneracy of each pathway. The bond lengths of the resulting complex were used as a guide for adjusting the frequencies of the vibrations in the complex. This complex should be adequate for an overall description of the rate of isomerization of methylcyclopropane. The construction of this model and the adjustment of the frequencies are described in Appendix II.

The Best Model

The vibrations which were changed in the various models are listed in Table 5-III. Table 5-III also includes some of the models DR tried (models 1-4). The various parameters, $\langle E \rangle$, $\log_{10} A$, k_{ω} , $(E_0 - E_a)$, etc., which were calculated from each model using the RRKM theory and each model are listed in Table 5-IV. Some of these models can be eliminated as being unrealistic by looking at Table 5-IV and comparing the calculated parameters with the experimental results. From Table 5-IV, it is obvious that complex 6 and 8 result in a k_{ω} at 763.8°K (and also at 720.1°K) that is much larger than experimentally observed. Models 1, 2, and 5 result in $\langle E \rangle$'s which are larger than $\langle E \rangle_{\max}$ for systems A, B, and C, and so can be discounted. Models 3 and 9 predict $\langle E \rangle$'s which are very close to the $\langle E \rangle_{\max}$ (only one kcal/mole less than $\langle E \rangle_{\max}$) for systems A and B. It is unlikely that all

of the excess energy of the ketene photolysis will go into the $^1\text{CH}_2$ and that, furthermore, $^1\text{CH}_2$ will carry all of that energy into the resulting methylcyclopropane and so models 3 and 9 are also unrealistic. Thus, only models 4, 7, 10, and 11 are left in the running and of these four, only model 7 involves all of the vibrations. As mentioned before, there is no good, a priori reason to assume that all of the vibrations are not involved in distributing the energy of the complex. Of course, all of these models assume the vibrations are harmonic, and especially if the complex has a lot of vibrational energy, which it does, the vibrations are more likely to be anharmonic. If the vibrations are anharmonic, it is even more probable that all of the vibrations are involved in distributing the energy.

Part of the empiricism of the RRKM treatment is that with enough small refinements, it would be possible to construct a model that fits the thermal data well, that results in $\langle E \rangle$'s within the allowed thermochemistry for the experimental rate constants, and that results in a difference in $\langle E \rangle$'s between the cyclopropane and propylene systems which is closer to that required by the heats of formation.¹⁴ Of course, as discussed above, the difference in $\langle E \rangle$'s in the cyclopropane and propylene systems may be smaller

14. Butler and Kistiakowsky used Kassel's classical limit for k_a (which is the same as Slater's) to find $\langle E \rangle$ and, although their systems were complicated by the presence of $^3\text{CH}_2$, the difference in $\langle E \rangle$'s was also much smaller than expected.

than the heats of formation predict because the reaction of $^1\text{CH}_2$ with propylene is faster than that with cyclopropane.

A Comparison of the Results of the RRKM Theory with Those of Other Theories

It is interesting to compare the results calculated from the RRKM treatment with those from the RRK theory (Rice, Ramsperger, and Kassel's¹⁵ theory, often referred to as Kassel's theory) and Slater's theory,¹⁶ even though they are less realistic than the RRKM theory. Since the energy of the complex in both the ketene-cyclopropane and the ketene-propylene systems is approximately 40 kcal/mole more than the critical energy, E_0 , required for isomerization, both theories approach the classical limit for k_a , i.e.,

$$k_a = A \left[\frac{\langle E \rangle - E_a}{\langle E \rangle} \right]^{s-1}$$

where A corresponds to the pre-exponential for the high pressure limit of the thermal isomerization, k_{∞} , and s is the adjustable parameter referred to as the number of effective oscillators.

Chesick found that with $s=18$, the statistical expression for

15. Rice, O. K. and Ramsperger, H. C., J. Am. Chem. Soc. 49, 1616 (1927); Kassel, L. S., J. Phys. Chem. 32, 225 (1928).

16. Slater, N. B., Theory of Unimolecular Reactions, Cornell University Press, Ithaca, N. Y., 1959.

k/k_{∞} in the RRK theory gave a good fit to his thermal data as expressed by a plot of the log of k/k_{∞} against the log of the total pressure. As shown in Table 5-VI, however, the $\langle E \rangle$'s corresponding to our experimental rates in the ketene photolysis system are larger than the thermochemical data allow. Using a smaller s results in smaller $\langle E \rangle$'s, however, as mentioned before, there is no reason to assume that the number of vibrations (or the number of oscillators) involved in a chemical activation system is smaller than in a thermal system. In those calculations where s is less than 18, although the $\langle E \rangle$'s decrease, the difference between the $\langle E \rangle$'s in systems A and C and also between the other systems also decreases. Placzek and Rabinovitch¹⁷ recalculated A and E_a from Chesick's⁴ data using only those experiments in which the pressure of methylcyclopropane was greater than 100 Torr. This was done in order to minimize any contribution of the decomposition of the olefins which occurs at lower pressures. The results presented in Table 5-VI were calculated using Placzek and Rabinovitch's values for A and E_a .

If the difference between the $\langle E \rangle$'s for the methylcyclopropane complex in the ketene-propylene system at 320 nm (system A) and the ketene-cyclopropane system at 313 nm (system C) is only the difference between the heats of formation and the small

E	120.0	18	106.3	15

Placzek and Rabinovitch's values for the thermal system:

$\log A = 15.25$ and $E_a = 64.3$ kcal/mole.

difference in photolyzing wavelengths, the classical limit of k_a can be solved for $\langle E \rangle$ for both systems. The number of oscillators, s , is not involved in this calculation. Using Placzek and Rabino- vitch's values for A and E_a , this calculation results in an $\langle E \rangle$ of about 111 kcal/mole for the methylcyclopropane complex produced in system A and 119 kcal/mole in system C. Both of these values for $\langle E \rangle$ are unacceptably high by more than 10 kcal/mole.

The Partitioning of Energy During the Photolysis of Ketene

Once the average energy of the complex is known, some of the details of the energy partitioning during the decomposition of ketene can be estimated. $\langle E \rangle_t$ is the average energy of the methylcyclopropane complex if none of the photolysis energy in excess of that required to decompose the ketene is carried by the $^1\text{CH}_2$ to the methylcyclopropane. $\langle E \rangle_{\text{max}}$ is the other extreme case, namely that in which all of the excess photolysis energy has been transferred to the $^1\text{CH}_2$ which does not lose any of this energy by collision before reacting to form methylcyclopropane, and in which the methylcyclopropane has received it all as vibrational energy. The fraction of the total energy available from the photolysis (the excess photolysis energy) that the methylcyclopropane has received as vibrational energy should be approximately the fraction of energy that the $^1\text{CH}_2$ has carried off from the photolytic

decomposition of ketene (plus or minus about 5 kcal/mole) and can be expressed as

$$f_E = \frac{\langle E \rangle - \langle E \rangle_t}{\langle E \rangle_{\max} - \langle E \rangle_t} .$$

$\langle E \rangle_t$ is 99.2 kcal/mole for the reaction of methylene and cyclopropane and 91.4 kcal/mole for the reaction of methylene and propylene. (See Table 5-VIII for a list of the heats of formation.) Table 5-VII lists the fraction of energy, f_E , the $^1\text{CH}_2$ carries off from the decomposition of ketene in each of the five systems studied. The $\langle E \rangle$'s used in the calculations are those predicted by our best model, model 7. Table 5-VII summarizes these results. The fraction of energy distributed to the $^1\text{CH}_2$ decreases as the photolyzing energy increases. This is not unexpected since the vibrational frequency of CO is 2174 cm^{-1} and the bending frequency in $^1\text{CH}_2$ is about 750 cm^{-1} ¹⁸ which means that when there is less energy available, it is more likely to go into the $^1\text{CH}_2$ than into the CO. Rabinovitch and his co-workers^{5,8} have estimated that 60 to 80 % of the available energy in the photolysis of ketene at 320 nm goes into the methylene.

A(330 nm)	0.7
C(313 nm)	0.6
D(277 nm)	0.5
E(214 nm)	0.3

Distribution of Isomers

Even though the isobutene and butene-1 were not completely resolved, some comments may be made about the distribution of the various butene isomers. When the methylcyclopropane is formed in our experiments, it has roughly 40 kcal/mole of energy in excess of the critical energy it needs to isomerize to any of the butenes. The distribution of the isomers will parallel the pre-exponential factors since the energy available is so much greater than the activation energies. (Table 5-IX is taken from Kinetic Data on Gas Phase Unimolecular Reactions by S. W. Benson and H. E. O'Neal (1970) NRSDS-NBS 21 and lists the thermochemical data for the methylcyclopropane isomerization.) Since the ratios of cis- to trans-butene-2 yields and the ratios of cis- and trans-butene-2 yields to the sum of the isobutene and butene-1 yields in our system are the same as found by Butler and Kistiakowsky¹, we can assume that the isomer distribution is approximately the same as in their experiments.

The rate constant for the isomerization of cis-butene-2 to trans-butene-2 is $\log k = 13.78 - 62.8 / (2.303 RT)$.¹⁹ At lower pressures, some of the cis-butene-2 will isomerize to trans-butene-2 since the cis isomer still has an excess of energy (as do the other isomers). At higher pressures, where the cis isomer has a

19. Rabinovitch, B. S. and Michel, K. W., J. Am. Chem. Soc. 81, 5065 (1959).

greater chance to be stabilized by collisions before isomerizing, the ratio of trans-/cis- butene-2 isomers should be smaller than that at lower pressures. This trend can be seen in the ratios in Table 5-I and is consistent with the results of Butler and Kistiakowsky,¹ Chesick,⁴ and Jakubowski, Sandhu, and Strausz.²⁰

Appendix I

Estimates of Radical Concentrations in the Ketene-IsobutaneExperiments

It is useful to have an estimate of the concentrations of the radicals in the ketene-isobutane system. Estimates were made for the steady-state concentrations of the radicals, CH_3 , $^1\text{CH}_2$, $^3\text{CH}_2$, and butyl radicals, in a typical photolysis of ketene and isobutane at 313 nm. The rate constants which were used were measured by other workers or were estimated using hard-sphere collision theory. It should be emphasized that the rate constants for the CH_2 reactions are not well known.

The mechanism outlined here is operative when no O_2 or CO has been added and when isobutane is the major component in the reaction system. The rate constants refer to the following reactions:

The values of the rate constants used were:

$k_2 = 3 \times 10^{-12}$	$\text{cm}^3/\text{molecule-sec}$	1
$k_{5s} = 3 \times 10^{-12}$		1, 2, and 3
$k_{4s} = 7 \times 10^{-12}$		1 and 9
$k_{3s} = 10^{-12}$		1 and 9
$k_{3t} = 2 \times 10^{-12}$		1 and 9
$k_{4t} = 0.03 \times 10^{-12}$		1 and 9
$k_{5t} = 4.6 \times 10^{-12}$		1 and 4
$k_8 = 4 \times 10^{-11}$		5
$k_9 = 0.5 \times 10^{-11}$		6
$k_{10} = 10^{-11}$		10 and values for k_9 and k_{11}
$k_{11} = 0.5 \times 10^{-11}$		estimate based on the value of k_9
$k_6 = 2.8 \times 10^{-11}$		{ 10 and the values of k_8, k_9 and k_{10}
$k_7 = 2.8 \times 10^{-11}$		
$k_{12} = 1.4 \times 10^{-11}$		
$k_{13} = 0.35 \times 10^{-11}$		
		7 and 9
		k_9, k_8 and 8

(If the reactions analogous to k_{12} and k_{13} were included for $(\text{CH}_3)_2\text{CHCH}_2^\bullet$, they would be negligible since their rate constants would be 0.1×10^{-11} and 0.04×10^{-11} , respectively. These numbers are estimated from hard sphere collision theory.)

A steady state treatment of the radicals for the mechanism on page I-1 results in the following equations:

$$[{}^1\text{CH}_2]_{ss} = \frac{\phi_s I_a}{(k_2 + k_{3s} + k_{4s}) [\text{IsoB}] + k_{5s} [\text{CH}_2\text{CO}]}$$

$$[{}^3\text{CH}_2]_{ss} = \frac{\phi_t I_a + k_2 [{}^1\text{CH}_2]_{ss} [\text{IsoB}]}{(k_{3t} + k_{4t}) [\text{IsoB}] + k_{5t} [\text{CH}_2\text{CO}]}$$

$$R_{\text{NeoP}} = k_{3s} [{}^1\text{CH}_2]_{ss} [\text{IsoB}] + k_6 [(\text{CH}_3)_3\text{C}\cdot][\text{CH}_3\cdot]$$

$$R_{\text{IsoP}} = k_{4s} [{}^1\text{CH}_2]_{ss} [\text{IsoB}] + k_7 [(\text{CH}_3)_2\text{CHCH}_2\cdot][\text{CH}_3\cdot]$$

$$R_{\text{Ethane}} = k_8 [\text{CH}_3\cdot]^2$$

$$R_{\text{OctB}} = k_9 [(\text{CH}_3)_3\text{C}\cdot]^2$$

$$R_{\text{OctA}} = k_{10} [(\text{CH}_3)_3\text{C}\cdot][(\text{CH}_3)_2\text{CHCH}_2\cdot]$$

$$R_{\text{OctC}} = k_{11} [(\text{CH}_3)_2\text{CHCH}_2\cdot]^2$$

The observable parameters for a typical experiment at 313 nm are:

$$I_a = 40 \times 10^{10} \text{ photons/sec-cm}^3$$

$$\text{IsoB} = 1.3 \times 10^{18} \text{ molecules/cm}^3$$

$$\text{CH}_2\text{CO} = 1.3 \times 10^{17} \text{ molecules/cm}^3$$

$$\phi_s = 0.80 \text{ and } \phi_t = 0.20$$

$$R_{\text{IsoP}} = 29 \times 10^{10} \text{ molecules/cm}^3\text{-sec}$$

$$R_{\text{NeoP}} = 8 \times 10^{10} \text{ molecules/cm}^3\text{-sec}$$

$$R_{\text{OctA}} = 0.25 \times 10^{10} \text{ molecules/cm}^3\text{-sec}$$

$$R_{\text{OctB}} = 1.2 \times 10^{10} \text{ molecules/cm}^3\text{-sec}$$

$$R_{\text{Ethane}} = 4 \times 10^{10} \text{ molecules/cm}^3\text{-sec}$$

Using the above equations and rate constants and the observed rates of formation, etc., the calculated steady-state concentrations and rates of formation are: (The rates of formation of neopentane and isopentane were calculated to serve as a check for the steady-state concentrations we calculated.)

$$[\text{CH}_3]_{ss} = 3.2 \times 10^{10} \text{ molecules/cm}^3$$

$$[(\text{CH}_3)_3\text{C}\cdot]_{ss} = 4.8 \times 10^{10} \text{ molecules/cm}^3$$

$$[(\text{CH}_3)_3\text{CHCH}_2\cdot]_{ss} = 1.3 \times 10^{10} \text{ molecules/cm}^3$$

$$[{}^1\text{CH}_2]_{ss} = 2.3 \times 10^4 \text{ molecules/cm}^3$$

$$[{}^3\text{CH}_2]_{ss} = 5.1 \times 10^4 \text{ molecules/cm}^3$$

$$R_{\text{IsoP}} = 21.1 \times 10^{10} \text{ molecules/cm}^3\text{-sec}$$

$$R_{\text{NeoP}} = 7.2 \times 10^{10} \text{ molecules/cm}^3\text{-sec}$$

$$R_{\text{OctC}} = 8.2 \times 10^6 \text{ molecules/cm}^3\text{-sec}$$

The agreement between the observed and calculated rates of formation of the pentanes is amazing considering all of the approximations and estimates involved. Assuming the calculations are correct, the fact that octane C was not observed among the products is not at all surprising, since it is calculated to be one-tenth the rate of formation of octane A, which itself was very small. The reaction of methyl and butyl radicals to form methane and isobutene, k_{13} , is negligible in this reaction system since, according to the values of the rate constants, this reaction would be one-eighth that of the recombination reaction to form neopentane.

Construction of the Model for Methylcyclopropane Decomposition

An illustration of the method used to construct the complex is given for butene-1.

The bond length for C-C bonds in the ring of methylcyclopropane is 1.53 \AA .¹ The C-C bond lengths in butene-1 are 1.54 \AA for the alkane C-C bonds and 1.34 \AA for the C-C double bonds. The bond angle between the carbons is 60° in the cyclopropane ring and the angle $C_1-C_2-C_3$ in butene-1 is 120° . We constructed a complex to describe the C_1-C_2 bond breaking. The $C_1-C_2-C_3$ angle was assumed to be 90° , the C_2-C_3 bond length 1.44 \AA , and the C_3-C_1 bond length 1.54 \AA . By simple geometry, the C_1-C_2 bond length must be 2.16 \AA . A similar model describes the C_1-C_3 bond breaking and is degenerate with the C_2-C_1 bond breaking. The superposition of the two complexes results in a triangular molecule with C_1-C_3 and C_1-C_2 bond lengths equal to 1.84 \AA and a C_2-C_3 bond length of 1.44 \AA . This complex has a weight of two when averaged with the other complexes because two hydrogens can migrate to form the same product. (The carbons, C_3 and C_2 were made equivalent when the two complexes were superimposed.)

A similar procedure was used in constructing the complexes for the other products. The final complex has bond lengths of 1.75 Å for the C₁-C₃ and C₁-C₂ bonds and a bond length of 1.62 Å for the C₂-C₃ bond. Since these bond lengths are to be used as a guide for adjusting the vibrational frequencies, an average bond length of 1.7 Å is an adequate estimate.

Frequency Assignments and Adjustments

Table 5-II (page 159) lists the frequency assignments for the cyclopropane ring according to Sverdlov and Krainov² and Herzberg¹.

Some of the rationale behind the frequency assignments made for the best model, complex 7 of Tables 5-III and 5-IV, is as follows. ν_3 is the completely symmetrical C-C stretch and was reduced by only 10% (corresponding to the 10% increase in the C-C bond lengths) since it cannot contribute significantly to the actual breaking of the ring. ν_4 , ν_5 , and ν_7 are symmetric in the sense that for each mode, the same motion occurs to all the carbons in the ring, and thus, neither of these modes can be particularly effective towards breaking the ring. These are bending modes and therefore, even though they are not very effective, they will be more effective than a symmetrical stretching mode. Consequently, we reduced the frequencies of these modes by 20%. ν_{10} and ν_{11}

were reduced by 30% because these are asymmetrical ring deformations which can contribute even more towards breaking the C-C bonds of the ring than any symmetrical motions.

According to Pauling's Rule for bond lengths and bond orders, a C-C bond length of 1.7 \AA corresponds to a bond order of 0.52. The two twisting of ν_{14} are most effective towards breaking the C-C bonds in the ring. These are bending motions and by a crude and simple-minded analogy to Badger's Rule, which relates the force constants of a vibration to the bond orders of the bonds involved, the frequencies of this twisting motion were reduced to 52% of the original frequencies.

The rocking motion of ν_{13} is probably not really effective towards breaking the C-C bonds in the ring, however, it can bring the H atoms closer to the other C atoms in the ring as the C-H bond is "rocked" towards the plane of the ring. For this reason, the frequency of the ν_{13} mode was reduced by 20%.

The other modes in methylcyclopropane do not directly contribute to the breaking of the cyclopropane ring and so were left unchanged.
